20. The recombinant nucleic acid of Claim 17, wherein said nucleic acid contains a sequence having a nucleotide identity of 90% or greater to SEQ ID NO:1, 2 or 3.

21. The recombinant nucleic acid of Claim 17, wherein said nucleic acid contains SEQ ID NO:1, 2 or 3.

22. The recombinant nucleic acid of Claim 17, wherein said sequence is obtainable from a plant species producing a hydroxylated fatty acid.

23. A recombinant nucleic acid suitable for use in Claim 1, wherein said nucleic acid contains a sequence encoding at least one of fatty acid desaturase or fatty acid hydroxylase.

24. The recombinant nucleic acid of Claim 23, wherein said sequence is obtainable from *Ricinus communis* (L.) (castor).

25. The recombinant nucleic acid of Claim 23, wherein said sequence is obtainable from *Lesquerella fendleri*.

26. The recombinant nucleic acid of Claim 23, wherein said nucleic acid contains a sequence encoding at least one of fatty acid desaturase or fatty acid hydroxylase in which one or more essential histidine residues have been mutated.

27. The method of Claim 1 further comprising: processing the seed containing the altered amount of the unsaturated fatty acid to obtain oil and/or seed meal.

28. Oil obtained by the method of Claim 27.

29. Seed meal obtained by the method of Claim 27.

30. Plant obtained by the method of Claim 1.

31. The method of Claim 11 further comprising: processing the seed containing the altered amount of the unsaturated fatty acid to obtain oil and/or seed meal.

32. Oil obtained by the method of Claim 31.

33. Seed meal obtained by the method of Claim 31.

34. Plant obtained by the method of Claim 11.

ALTERED LINOLENIC AND LINOLEIC ACID CONTENT IN PLANTS

This is a continuation-in-part of U.S. Serial No. 08/156,551 filed November 22, 1993, which is a continuation of U.S. Serial No. 08/014,431, filed on February 5, 1993. The present invention relates to genetically engineered plants. In particular it relates to genetically engineered plants and seeds which have altered linolenic and linoleic acid content compared with naturally occurring plants.

BACKGROUND

Many crop species produce seed oils in which the fatty acid composition is not ideally suited to the intended use. The application of conventional breeding methods, coupled in some cases with mutagenesis, has resulted in the production of new varieties of several species with desirable alterations in the fatty acid composition of seed oil. A notable example is the development of low erucic acid varieties of rapeseed (Stefansson 1983). Similar efforts have resulted in the reduction of the level of polyunsaturated 18-carbon fatty acids in soybean (Wilcox and Cavins 1985; Graef et al. 1988), sunflower (Fick 1989), and linseed oils (Green and Marshal 1984).

Most of the genetic variation in seed lipid fatty acid composition appears to involve the presence of an allele of a gene that disrupts normal fatty acid metabolism and leads to an accumulation of intermediate fatty acid products in the seed storage lipids (Downey 1987). However, it seems likely that, because of the inherent limitations of this approach, many other desirable changes in seed oil fatty acid composition may require the directed application of genetic engineering methods.

α-Linolenic acid ($18:3^{\Delta 9,12,15}$) is an eighteen carbon fatty acid containing three *cis* double bonds at the 9-10, 12-13 and 15-16 carbons. It is found in the cells of higher plants as a constituent of cell membranes. It

is also found in storage organs, such as in seeds. There it is designated oil bodies which are bounded by an electron dense structure that is thought to be a half-unit membrane and dispersed in the cytoplasmic environment of cells. When present as a constituent of cell membranes, linolenic acid is usually esterified to the sn-1 or sn-2 position of the glycerol moiety of a diacyl-glycerolipid. By contrast, when present in oil bodies, linolenic acid is usually esterified to the sn-1, sn-2 or sn-3 position of a triacylglycerolipid (TAG).

Linolenic acid is extensively used in the paint and varnish industry in view of its rapid oxidation. Flax seed is a predominant source of this oil. Soybean seed, on the other hand, does not have sufficient linolenic acid content to be used in this industry. Thus, increasing the linolenic acid content in a plant such as soybean would permit the use of the soybean oil in the paint and varnish industry.

On the other hand, it is undesirable to have significant levels of linolenic acid in cooking oils and foods. Linolenic acid is unstable during cooking and is rapidly oxidized. The oxidized products impart rancidity to the finished product. A rapeseed or soybean oil with reduced linolenic acid, such as containing 2% or less of linolenic acid, would be ideal for use as a cooking oil.

Linolenic acid is also a precursor in the biosynthesis of jasmonic acid, an important plant growth regulator. Linolenic acid is converted to jasmonic acid by introduction of an oxygen to the carbon chain by a lipoxygenase, followed by dehydration, reduction, and several β-oxidations (Vick and Zimmerman, 1984). The activity of jasmonic acid has been measured in terms of induction of pathogen defense responses. By application of free linolenic acid to plants, plant pathogen defenses can also be induced (Farmer and Ryan, 1992).

A model has been proposed to explain the ability of free linolenic acid to exhibit the effects associated with jasmonic acid (Farmer and Ryan, 1992). It is hypothesized that all of the enzymatic activities which are required for the conversion of linolenic acid to jasmonic acid are constitutively present in the cell and the rate limiting step in the production of jasmonic acid is the availability of free linolenic acid. A likely route for the production of the free linolenic acid is by the activity of a lipase in the plasma membrane.

It has been observed that exogenous jasmonic acid can more powerfully activate defense responses than can wounding. This suggests that wounds cannot generate enough free linolenic acid to support high level production of jasmonic acid. The activity of the lipase or the availability of appropriate substrate for the lipase may be rate limiting upon wounding. Thus, increasing the linolenic acid content of plasma membrane may positively influence "signal transduction" in plants and result in better protection against environment and pathogen stress.

Linolenic acid, as well as oleic and linoleic acids are also important constituents, as well as precursors of volatile carbonyl compounds, whic contribute to the aroma of both fresh and cooked foods. The major fatty acids of tomato fruit pericarp are oleic, linoleic and linolenic acids. As the fruit ripens, the levels of the latter two fatty acids decline resulting in the production of a number of 4-6 carbon containing aldehydees and ketones. One particular metabolite, *cis*-3-hexanol, has been shown to be present in higher levels in vine-ripened tomatoes compared to supermarket tomatoes or tomatoes stored in refrigerators. It is likely, therefore, that the "aroma" of fresh fruits and vegetables can be "modulated" by regulation of the content of linolenic and linoleic acids, important substrates for the enzyme lipoxygenase and subsequently the

hydroperoxide cleaving enzyme, which generates the volatile "aroma" compounds.

From the above, it is clear that the ability to vary the content of linolenic acid in plants would be desirable. However, to achieve this result it is necessary to determine what controls the product of linolenic acid in plants.

A large body of experimental evidence derived from radiochemical tracer studies has indicated that α-linolenic acid is synthesized by the desaturation of linoleic acid ($18{:}2^{\Delta 9,12}$) (reviewed in Harwood 1988;). However, the actual substrate for desaturation is not known.

In vivo and *in vitro* labelling studies suggest that there are possibly two distinct pathways for the synthesis of linolenic acid (Browse and Somerville, 1991). One possible pathway is thought to be located in the endoplasmic reticulum where linoleic acid esterified to the sn-2 position of phosphatidylcholine is a substrate for desaturation. However, the available evidence does not exclude the possibility that linoleic acid esterified to other lipids may also be a substrate.

A second possible pathway of linoleic acid desaturation is located in the plastid where the available evidence suggests that linoleic acid esterified to monogalactosyldiacylglycerol and, possibly, other plastid lipids is the substrate for desaturation.

Relatively little direct information is available concerning the enzymes involved in linoleic acid desaturation. Low levels of enzyme activity have been detected in microsomal membrane preparations from developing linseed (Linum ussitatum) (Browse and Slack, 1981) and, more recently, in preparations of gently lysed chloroplasts (Schmidt and Heinz, 1990a,b). The general features of the enzyme may be inferred from information available about other enzymes of this class.

The most thoroughly characterized desaturase is the stearoyl-Coenzyme A (CoA) desaturase from vertebrate liver (reviewed by Holloway, 1983). This enzyme has been shown to be an integral membrane protein which contains non-heme iron. The desaturase reaction requires fatty acyl-CoA, molecular oxygen and reduced cytochrome b5, another membrane protein. *In vivo*, the reduced cytochrome b5 is produced by the transfer of reducing equivalents from NADH via the activity of cytochrome b5 reductase, a flavin containing membrane protein.

The most thoroughly characterized desaturase from plants is the stearoyl-ACP desaturase (McKeon and Stumpf, 1982; Shanklin and Somerville, 1991). This enzyme also requires molecular oxygen and a high potential reductant. However, in contrast to the animal enzyme, this desaturase is a soluble plastid protein which preferentially acts on a fatty acid esterified to acyl carrier protein (ACP) rather than CoA. This enzyme also differs from the animal enzyme by utilizing reduced ferredoxin as an intermediate electron donor.

Other plant desaturases appear to be membrane proteins. The microsomal Δ12 oleate desaturase from several plant species has been assayed in membrane preparations from several plants (Harwood, 1988). As with the stearoyl-CoA desaturase from animals, this enzyme requires molecular oxygen and reduced cytochrome b5 as an electron donor (Kearns et al., 1991). However, it appears that oleate esterified to a phospholipid is the substrate rather than a CoA ester.

With regard to the activity responsible for the making of linolenic acid, little was known as to its source or origin. However, evidence that the amount of linolenic acid is related to the amount of linoleic acid desaturase activity has been obtained by analysis of the properties of the fad3 mutant of *Arabidopsis thaliana* (Lemieux et al. 1990). This mutant is deficient in linolenic acid in the storage oils of its seed lipids and in the

membrane lipids of different tissues to varying degrees. The mutant also had an increase in the amount of linoleic acid. This can be interpreted as evidence that the mutant is defective in the activity of a desaturase which converts linoleic acid to linolenic acid.

There is further evidence to suggest that the activity of this desaturase could be rate limiting for linolenic acid synthesis under normal circumstances. This was discovered by measuring the effects on fatty acid composition in heterozygous plants (i.e., fad3+/fad-) formed by crossing the wild type with the fad3 mutant. In these F1 plants, which have one copy of the normal fad3 gene product instead of the two normally found in the wild type, the amount of linolenic acid was almost exactly intermediate between that found in either parent. This suggests that the amount of linolenic acid is proportional to the amount of functional fad3 gene product (Lemieux et al., 1990).

These results do not shed any light, however, on the nature of the fad3 gene product or whether the observed effects in mutants are related to either a decrease in quantitiy of desaturase protein or desaturase activity due to a defective protein.

Moreover, nothing is known with any degree of certainty about the linoleic acid desaturase from plant microsomes. As noted above, very little is known about the microsomal desaturases except that they probably utilize reduced cytochrome b5 as intermediate electron donor and probably utilize lipids rather than CoA or ACP esters as substrates.

Moreover, as in many other aspects of plant biology, the lack of specific information about the biochemistry and regulation of lipid metabolism makes it difficult to predict how the introduction of one or a few genes might usefully alter seed lipid synthesis.

An additional problem arises from the fact that many of the key enzymes of lipid metabolism are membrane-bound and present in low

quantities. Thus, attempts to solubilize and purify them from plant sources have not been successful.

SUMMARY OF THE INVENTION

The present invention provides structural coding sequences encoding linoleic acid desaturase activity which can be used to alter the linoleic and linolenic acid compositions of plants or to isolate other plant linoleic acid desaturases. The present invention further provides a plant capable of expressing a structural coding sequence to control the level of linolenic acid or linoleic acid or both in the plant. The present invention further provides a method for controlling the levels of linoleic and linolenic acid in plants. It is also demonstrated by the present invention that the linoleic acid desaturase enzyme activity in plant cells and tissues is a controlling step in linolenic acid biosynthesis.

The present invention further relates to the engineering of two advantageous traits into plants: increased and decreased α–linolenic acid content in the structural lipids or storage oils of various crop plants.

In accomplishing the foregoing, there is provided, in accordance with one aspect of the present invention, a genetically transformed plant which has an elevated linolenic acid content comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

In accordance with another aspect of the present invention, there is provided a genetically transformed plant which has a reduced linolenic acid content, comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

There has also been provided, in accordance with another aspect of the present invention a method of producing a genetically transformed plant which has an elevated or reduced linolenic acid content. There has also been provided, in accordance with another aspect of the present invention a recombinant, double-stranded DNA molecule and plant cells containing a recombinant, double-stranded DNA molecule.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 shows the genetic map of the region of chromosome 2 of *Arabidopsis thaliana* where a linoleic acid desaturase gene is located and the identity of the yeast artificial chromosomes which carry this region of the genome.

Figure 2 shows the structure of plasmid pBNDES3 which was obtained by inserting an EcoRI fragment containing the *B. napus* linoleic acid desaturase cDNA (fad3) into pBLUESCRIPT.

Figure 3 shows the nucleotide sequence (SEQ ID NO:1) and deduced amino acid sequence (SEQ ID NO:2) for the linoleic acid desaturase cDNA (fad3) from *B. napus*.

Figure 4 shows a comparison of the deduced amino acid sequence of one linoleic acid desaturase cDNA (fad3) from *B. napus* and the desA gene from *Synechocystis*. Identical residues are indicated by a solid box. Conservative substitutions are indicated by a stippled box.

Figure 5 shows the binary Ti plasmid vector pBI121.

Figure 6 shows the binary Ti plasmid pTiDES3 which was constructed by insertion of a linoleic acid desaturase cDNA (fad3) into pBI121.

Figure 7 shows the map of the plant transformation vector pMON13804.

Figure 8 shows the map of the plant transformation vector pMON13805.

Figure 9 shows the oil content of control and transformed canola seed in accordance with the present invention.

Figure 10 shows the nucleotide sequence (SEQ ID NO:9) for the linoleic acid desaturase cDNA (fadD) from *Arabidopsis*.

Figure 11 shows the deduced amino acid sequence (SEQ ID NO:10) for the linoleic acid desaturase cDNA (fadD) from *Arabidopsis*.

Figure 12 shows the nucleotide sequence (SEQ ID NO:11) for the linoleic acid desaturase cDNA (fadE) from *Arabidopsis*.

Figure 13 shows the deduced amino acid sequence (SEQ ID NO:12) for the linoleic acid desaturase cDNA (fadE) from *Arabidopsis*.

DETAILED DESCRIPTION OF THE INVENTION

A genetically transformed plant of the present invention which has an altered linolenic or linoleic acid content can be obtained by

expressing the double-stranded DNA molecules described in this application.

The expression of a double-stranded DNA involves transcription of messenger RNA (mRNA) from one strand of the DNA by RNA polymerase enzyme, and the subsequent processing of the mRNA primary transcript inside the nucleus. This processing involves a 3' non-translated region which adds polyadenylate nucleotides to the 3' end of the RNA.

Promoters

Transcription of DNA into mRNA is regulated by a region of DNA usually referred to as the "promoter." The promoter region contains a sequence of bases that signals RNA polymerase to associate with the DNA, and to initiate the transcription of mRNA using one of the DNA strands as a template to make a corresponding complementary strand of RNA.

Any promoter which is known or is found to cause transcription of RNA in plant cells can be used in the present invention. Promoters which are useful in the present invention include any promoter that functions in a plant cell to cause the production of a RNA sequence. A number of promoters which are active in plant cells and are capable of producing a RNA sequence have been described in the literature. These include the nopaline synthase (NOS) and octopine synthase (OCS) promoters (which are carried on tumor-inducing plasmids of Agrobacterium tumefaciens), the caulimovirus promoters such as the cauliflower mosaic virus (CaMV) 19S and 35S and the figwort mosaic virus 35S-promoters, the light-inducible promoter from the small subunit of ribulose-1,5-bis-phosphate carboxylase (ssRUBISCO, a very abundant plant polypeptide), and the chlorophyll a/b binding protein gene promoter, etc. All of these promoters have been used to create various types of DNA constructs

which have been expressed in plants; see, e.g., PCT publication WO 84/02913 (Rogers et al., Monsanto).

Promoters may be obtained from a variety of sources such as plants and plant viruses. Promoters can be used in the form that they exist as isolated from plant genes such as ssRUBISCO genes, or can be modified to improve their effectiveness, such as with the enhanced CaMV35S promoter.

Those skilled in the art will recognize that the amount of linoleic acid desaturase needed to induce the desired alteration in linolenic acid content may vary with the type of plant. It is also possible that extremes in linoleic acid desaturase activity may be deleterious to the plant. Therefore, in a preferred embodiment, promoter function should be optimized by selecting a promoter with the desired tissue expression capabilities and approximate promoter strength and selecting a transformant which produces the desired linoleic acid desaturase activity in the target tissues.

This selection approach from the pool of transformants is routinely employed in expression of heterologous structural genes in plants since there is variation between transformants containing the same heterologous gene due to the site of gene insertion within the plant genome. (Commonly referred to as "position effect").

In a preferred embodiment, the promoters utilized in the double-stranded DNA molecules should have relatively high expression in tissues where the increased or decreased linolenic acid content is desired, such as the seeds of the plant. In Canola, a particularly preferred promoter in this regard is the seed specific promoter described herein in greater detail in the accompanying examples.

In another preferred embodiment, the promoter used in the expression of the double-stranded DNA molecules of the present invention

can be a constitutive promoter, expressing the DNA molecule in all or most of the tissues of the plant. However, the promoter selected for this embodiments should not cause expression at levels which are detrimental to plant health, growth and development.

ß-conglycinin (also known as the 7S protein) is one of the major storage proteins in soybean (Glycine max) (Meinke et al., 1981). The 7S (β-conglycin) α'-subunit promoter, used in one aspect of this study to express the linoleic acid desaturase gene, has been shown to be both highly active and seed-specific (Doyle et al, 1986 and Beachy et al., 1985). The ß-subunit of ß-conglycinin has been expressed, using its endogenous promoter, in the seeds of transgenic petunia and tobacco, showing that the promoter functions in a seed-specific manner in other plants (Bray et al., 1987). The promoter for ß-conglycinin could be used to in accordance with the present invention. If used, this promoter could express the DNA molecule specifically in seeds, which could lead to an alteration in the linolenic acid content of the seeds.

In addition, the endogenous plant linoleic acid desaturase promoters can be used in the present invention. These promoters should be useful in expressing a linoleic acid desaturase gene in specific tissues, such as leaves, seeds or fruits. A number of other promoters with seed-specific or seed-enhanced expression are known and are likely to be expressed in seeds, which are oil accumulating cells. For illustration, the napin promoter and the acyl carrier protein promoters have been utilized in the modification of seed oil by antisense expression (Knutson et al., 1992).

The linolenic acid content of root tissue can be increased by expressing a linoleic acid desaturase gene behind a promoter which is expressed in roots. The promoter from the acid chitinase gene (Samac et al., 1990) is known to function in root tissue and could be used to express the linoleic acid desaturase in root tissue. Expression in root tissue could

also be accomplished by utilizing the root specific subdomains of the CaMV35S promoter that have been identified. (Benfey et al., 1989). The linolenic acid content of leaf tissue can be increased by expressing the linoleic acid desaturase gene using a leaf active promoter such as ssRUBISCO promoter or chlorophyll a/b binding protein gene promoter.

The linolenic acid content of fruits can be increased by expressing a linolenic acid desaturase gene behind a promoter which is functional in fruits. Such promoters could be either expressed at all developmental stages of the fruit or restricted to specific stages, particularly fruit ripening.

The RNA produced by a DNA construct of the present invention can also contain a 5' non-translated leader sequence. This sequence can be derived from the promoter selected to express the gene, and can be specifically modified so as to increase translation of the mRNA. The 5' non-translated regions can also be obtained from viral RNAs, from suitable eukaryotic genes, or from a synthetic gene sequence. The present invention is not limited to constructs, as presented in the following examples, wherein the non-translated region is derived from the 5' non-translated sequence that accompanies the promoter sequence. Rather, the non-translated leader sequence can be derived from an unrelated promoter or coding sequence as discussed above.

Linoleic Acid Desaturase Structural Coding Sequences

The structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity can be the sequences disclosed in the present application, or any sequence that can be obtained using the sequences disclosed in the present application, or any sequence that can be isolated using the method disclosed in the present application.

The structural coding sequence can also be a part of or from the structural coding sequences disclosed in the present invention. It is possible that the active part of the linoleic acid desaturase is formed using only part of the structural coding sequences disclosed in the present application.

The structural coding sequences can be obtained from a variety of sources, such as algae, bacteria or plants. Preferably, structural coding sequences obtained from plants are used in accordance with the present invention.

Since virtually nothing was known about the properties of the linoleic acid desaturase structural coding sequence prior to the present invention, the method used in the present invention to isolate the structural coding sequence was based on the concept of map based cloning. The essential concept in map based cloning is to use information about the genetic map position of a structural coding sequence to isolate the region of the chromosome surrounding the structural coding sequence, and then to use the isolated DNA to complement a mutation in the structural coding sequence. This strategy has never previously been reported in the isolation of any plant gene.

In order to implement map based cloning of the linoleic acid desaturase, mutants of *Arabidopsis thaliana* (L.) deficient in linoleic acid desaturase activity were isolated by screening randomly chosen individuals from mutagenized populations of plants for individual plants with altered leaf or seed fatty acid composition. (Browse et al. 1985; Lemieux et al. 1990). By screening thousands of plants for altered fatty acid composition, mutants with decreased amounts of linolenic acid and increased amounts of linoleic acid in leaf and seed lipids were isolated. Physiological and genetic analyses of these mutants indicated that they fell into three complementation groups designated fad3, fadD and fadE.

The fad3 mutants had very reduced levels of linolenic acid in seeds and roots but had almost normal levels of linolenic acid in leaves. This effect was interpreted as evidence that the fad3 locus encoded a microsomal desaturase which was responsible for desaturation of linoleic acid to linolenic acid on lipids made by the pathway of lipid biosynthesis in the endoplasmic reticulum, designated the "eukaryotic pathway" (Lemieux et al. 1990). This pathway is mostly responsible for the synthesis of lipids in non-green tissues such as seeds and roots, but plays a secondary role in leaves and other green tissues. Thus, a mutation in the fad3 gene would not be expected to have a major effect on the desaturation of leaf lipids.

In contrast to the fad3 mutant, the fadD mutant had almost normal fatty acid composition of roots and seeds, but had a strong reduction in the amount of linolenic acid in leaf lipids, and a corresponding increase in the amount of linoleic acid. (Browse et al., 1986). Thus, this mutant had the properties expected of a mutant deficient in a linoleic acid desaturase from the prokaryotic pathway which is primarily responsible for the synthesis of lipids in green tissues.

An unusual property of the fadD mutants was that they were very deficient in linoleic acid content when grown at temperatures above about 22 °C but had almost normal fatty acid composition when grown at temperatures below about 18 °C (McCourt et al., 1987). Since it was very unlikely that several independently isolated mutations would all give rise to a temperature conditional phenotype, it was concluded that a second desaturase must be partially responsible for desaturating linoleic acid to linolenic acid in green tissues. Therefore, the fadD mutant was remutagenized with ethylmethane sulfonate, self-fertilized to produce a segregating population of mutagenized plants (designated the M2 generation), and this population was screened for a mutant which was deficient in linolenic acid in green tissues at low temperatures. A mutant

with this property was isolated and the mutation responsible for this effect was designated the fadE locus (Somerville and Browse, unpublished).

Isolation of the Linoleic Acid Desaturase Gene from Canola

The following example was used to isolate the structural coding sequence from the fad3 region. The method described herein could equally have been used to isolate either the fadD or fadE region.

In order to approximately locate the fad3 mutation of the genetic map of *Arabidopsis*, a sexual cross was made between the fad3 mutant line BL1 and the multiply marked mutant line W1 (Hugly et al., 1991). The F1 hybrids from this cross were permitted to self-fertilize and the resulting F2 plants were scored for both the segregating genetic markers and the altered fatty acid composition. The results of this analysis indicated that the fad3 mutation was located on chromosome 2 near the marker erecta. In order to obtain a more accurate map position by RFLP mapping, a second sexual cross was made between the fad3 mutant line BL1 and the Niederzenz race of *Arabidopsis*. The F1 progeny were permitted to self-fertilize to produce the F2 generation. 137 F2 plants were grown during 3 weeks at 22° C (100 $\mu E/m^2/s$) in order to produce fully expanded rosettes, and a few leaves (representing a total weight of 0.2-0.5 g per plant) were harvested from each plant in order to prepare DNA from them.

The leaves were frozen in liquid nitrogen, and ground in dry ice, using a mortar and a pestle. For each sample, the frozen powder was transferred to a microfuge tube and an equal amount of 2 X CTAB buffer (2% cetyltrimethyl ammonium bromide (CTAB), 100 mM Tris-HCl pH 8, 20 mM EDTA, 1.4 M NaCl, 1% polyvinylpolypyrrolidone (PVP) 40,000) was added. The tubes were left at room temperature for 5 min to allow the powder to thaw. The homogenate was extracted once with a mixture of chloroform-isoamyl alcohol (24:1, v/v), and 1/10 vol of 10 X CTAB (10 % CTAB, 0.7 M NaCl) buffer was added to the aqueous phase, which was then

reextracted with an equal volume of chloroform isoamyl alcohol (24:1, v/v). The aqueous phase was transferred to a fresh microfuge tube and 1.5 vol of CTAB precipitation buffer (1% CTAB, 50 mM Tris-HCl pH 8, 10 mM EDTA) was added. The DNA was allowed to precipitate for 12 hr at 4 degrees, and collected by centrifugation (5 min at 10 000g). The DNA was resuspended in 100 µl of 10 mM Tris-HCl pH 7.5, 1 mM EDTA, 1 M NaCl, and 100 µg/ml RNase A and incubated at 50°C for 30 min. The DNA was precipitated by adding 2.2 vol of ethanol and incubating on ice for 20 min. The DNA was collected by centrifugation and the pellet was washed once with 1 ml of 70% ethanol, dried under vacuum for 3 min and resuspended in 10 µl of distilled water. The DNA was stored at -20°C until use.

The 137 plants were grown to maturity and their seeds were collected individually. The fatty acid composition of 10 individual seeds from each of the F2 plants was measured as described by Browse et al (1986) in order to score the fad3 phenotype of each plant. Each seed was incubated in 1 ml of 1N HCl in methanol for 1h at 80°C. The tubes were cooled to room temperature and 1 ml of 0.9 % NaCl plus 0.3 ml of hexane were added. The tubes were agitated by vortexing and the phases separated by centrifugation (300xg for 5 min). The hexane phase was saved, evaporated under a stream of nitrogen, and the fatty acid methyl esters were dissolved in 50 µl hexane. An aliquot (2 µl) was injected onto the gas chromatograph and the fatty acid methyl esters separated and quantitated by flame ionization as described (Browse et al., 1986).

The DNA samples (1 µg) were then cut with the appropriate restriction enzyme (EcoR1 for the marker # 220, Bgl2 for the marker ASA2) using a concentration of 1XKGB buffer (Sambrook et al, 1989), 5 units of the restriction endonuclease and 100 µg/ml BSA. The volume of each sample was 10 µl and the incubation was performed at 37 °C for 4 h. The fragments were resolved by agarose gel electrophoresis (0.8 % agarose

in 1X TAE buffer; Sambrock et al., 1989) and transferred to nylon filters (hybond N+), using the alkaline transfer method as described by the manufacturer. The nylon filters were probed (according to Church and Gilbert, 1984) with radioactively labelled fragments of DNA (Sambrock et al., 1989) corresponding to known RFLP markers which had previously been mapped in the approximate vicinity of the fad3 locus on chromosome 2. The RFLP markers 220 (Chang et al 1988) and ASA2 were found to map close to the fad3 locus. Analysis of the pattern of recombinants (Table 1) indicated that both ASA2 and 220 were located on the same side of the fad3 locus at distances of 0.4 and 2.2 centimorgans (cM), respectively.

Table 1

# of plants	220	ASA2	fad3
67	H	H	+/-
30	L	L	-/-
34	N	N	+/+
3	H	N	+/+
1	L	H	+/-
1	N	H	+/-
1	H	H	-/-

Table 1 shows the genotype of the F2 plants used for mapping the fad 3 locus. L is for Landsberg (background of the fad 3 mutant), N is for Niederzenz, H for heterozygous. A total of 137 F2 plants were analyzed. The number of recombinant plants between fad3 and 220 or ASA2 was 6 and 1 respectively.

In order to isolate the region of the chromosome containing the fad3 locus, the RFLP markers 220 and ASA2 were used as hybridization probes to screen several yeast artificial chromosome (YAC) libraries. (Grill

and Somerville, 1991; Ward and Jen, 1990). The YAC filters were prepared according to Grill and Somerville (1991). The library was replicated onto nylon filters disposed on petri dishes of SC – – (synthetic complete medium minus tryptophan and uracil; Sherman et al., 1986). The cells were allowed to grow for 12 h at 30°C, and the filters were transferred for 15 min on a Whatman 3MM paper saturated with 1 M sorbitol, 50 mM DTT, 50 mM EDTA (pH 8).

The cell wall of the cells was then digested with lyticase, by incubating the filters on a Whatman paper saturated with 1M sorbitol, 50 mM EDTA and 2 mg/ml lyticase (Sigma Co., St. Louis,MO) for 12 h at 30°C. The filters were then transferred on a Whatman 3MM paper saturated with 0.5 M NaOH, 1.5 M NaCl for 15 min, neutralized with 0.5 M Tris-HCl pH 8 for 15 min and quickly rinsed in 2XSSC (SSC is 10mM sodium citrate, 150mM NaCl, pH 7). The filters were allowed to dry, and were transferred to a vacuum oven at 80°C for 1 h. They were subsequently hybridized according to Church and Gilbert (1984), with probes labelled with ^{32}P according to Sambrook et al. (1989).

The DNA of RFLP probe 220 was prepared from 100 ml of liquid culture lysate using the lambdasorb procedure (Promega Corp., Madison, WI); the cDNA encoding ASA2 was excised from the original plasmid (pKN140C; obtained from Dr. G. Fink, Whitehead Institute, Cambridge, MA) with Hind3 and cloned into the Hind3 site of pBLUESCRIPT. The plasmid DNA was then purified by Cesium chloride gradients according to Sambrook et al (1989), digested with Hind3 and the DNA insert was gel purified twice by electroelution according to Sambrook et al (1989).

In order to probe the libraries, the whole DNA from RFLP220 was used as a hybridization probe. By contrast, only the DNA insert of ASA2 was used as a probe. The RFLP probe 220 hybridized to YAC

EG4E8 and EG9D12. The probe ASA2 hybridized to YACs EW15G1, EW15B4 and EW7D11.

In order to determine if these YACs contained all of the DNA between RFLP220 and ASA2, small regions of DNA from the ends of the inserts in EG4E8 and EW15G1 were prepared by inverse PCR (Grill and Somerville, 1991). For that purpose, DNA was prepared from the appropriate YAC clones. The clones (single colonies) were grown to saturation in SC– – liquid cultures, and 1 ml of these cultures was used to inoculate 40 ml liquid cultures (in SC– – medium) that were allowed to grow for 16 h at 30°C. The cells were collected by centrifugation, washed once in 1 M sorbitol, 50 mM EDTA, resuspended in 200 μl of 1 M sorbitol, 50 mM EDTA, 100 mM sodium citrate pH 5.8, 2 mM β-mercaptoethanol and 2 mg/ml lyticase, and incubated 2 h at 30 °C.

Next, 350 μl of 2XCTAB buffer was added and the DNA was purified as described above. DNA (5 μg) of each clone was digested separately with HincII, AluI, EcoRV and RsaI (in 1XKGB buffer, at 37 °C for 4 h; final volume: 50 μl). The reactions were stopped by heating at 65 °C for 15 min, extracted once with one volume of phenol saturated with TE pH 8, followed by an extraction with 1 volume of chloroform - isoamyl alcohol mixture (24:1, vol/vol). The DNA was recovered by ethanol precipitation and resuspended in sterile distilled water. The ligation reactions were performed using 300 ng of DNA in a final volume of 50 μl. The reactions were carried out in 50 mM Tris-HCl pH 7.4, 10 mM MgCl2, 1 mM DTT,1.2 mM ATP with 1 U of ligase, for 2 h at 20 °C, and stopped by heating at 68 °C for 30 min.

The PCR reactions were carried out as follows: The buffers used were the ones indicated by the suppliers except for the Perkin Elmer enzyme for which the reaction was supplemented with an additional 1.4 mM $MgCl_2$ (final concentration 2.9 mM Mg). The dNTP final concentration

was 125 µM when the Perkin Elmer enzyme was used and 200 µM with the Taq polymerases from other sources. In all cases, 100 ng of each oligonucleotide was used. The final volume was 100 µl. When no product was obtained, the reactions were carried out again in the same conditions except that formamide was added to a final concentration of 3 %.

The left end was amplified from the ligation products of the EcoRV and RsaI digests, using the oligonucleotides EG1 (GGCGATGCTGTCGGAATGGACGATA) (SEQ. ID NO. 3) and EG2 (CTTGGAGCCACTATCGACTACGCGATC) (SEQ. ID NO. 4).

The right end of the clones obtained from the EG library was amplified from the ligation products of the AluI and HincII digests, using the oligonucleotides EG3 (CCGATCTCAAGATTACGGAAT) (SEQ. ID NO. 5) and EG4 (TTCCTAATGCAGGAGTCGCATAAG) (SEQ. ID NO. 6).

The right end of the clones obtained from the EW YAC library was amplified using the oligonucleotides H1 (AGGAGTCGCATAAGGGAG) (SEQ. ID NO. 7) and H2 (GGGAAGTGAATGGAGAC) (SEQ. ID NO. 8), using the same cycle conditions as above, except that the annealing temperature was reduced to 50 °C.

After the reactions were completed, 5µl of each mixture were electrophoresed on an agarose gel to separate the amplification product from primers. The slice of agarose that contained the amplified band was excised from the gel and melted in 1 ml of distilled water. Large amounts of product could then be produced, by reamplification of 5 µl of the melted slice. The PCR products were then purified by electroelution or by using GeneClean (Bio101) and used as hybridization probes to probe filters containing the isolated YAC DNA restricted by several enzymes. The probe made from the right end of EW15G1 hybridized to EG4E8 and similarly, a probe from the right end of EG4E8 hybridized to EW15G1.

Thus, it was concluded that the YACs EG4E8 and EW15G1 contained all of the DNA in the region of the chromosome between RFLP220 and ASA2.

The size of the YAC clones was estimated by field inversion electrophoresis (CHEF, Vollrath and Davis, 1987). High molecular weight DNA was prepared as follows: the yeast cells which contained the YAC clones were grown and treated with lyticase as for preparing DNA as described above. The spheroplasts were then resuspended in an equal volume of 1M sorbitol, 50 mM EDTA, 1 % low melt agarose at 37°C. The mixture was poured in a mould (Biorad) which was set on ice to allow the agarose to harden.

The resulting plugs were incubated for 12 h in 0.5 M EDTA pH 9, 1% lauryl sarcosine 1 mg/ml Proteinase K at 50°C. The plugs were subsequently washed twice in 50 mM EDTA and stored at 4°C until use. The CHEF gel was run in 1XTBE for 16 h at 200 V, with a switching interval of 20 s; the temperature of the buffer was maintained at 14 °C during the run. The sizes of the YACs were determined by comparison with a lambda ladder and the yeast chromosomes, and were as follows: EG4E8, 90 kb; EG9D12, 190 kb; EW15G1, 90 kb; EW15B4, 70 kb, EW7D11, 125 kb. These sizes permitted us to roughly determine a correspondence between physical and genetic distances: the distance that separates 220 from ASA2 cannot exceed 180 kb, the sum of the size of the 2 YACs EG4E8 and EW15G1. Since the corresponding genetic distance is 1.7 cM, one can roughly estimate that, in this particular cross and in this particular region of the genome, the value of 1 cM is close to 100kb. Thus, since the fad3 gene maps only 0.4 cM away from ASA2, the corresponding physical distance should be close to 40 kb. We then concluded that fad3 was probably located on the YAC EW7D11, which is the largest YAC hybridizing with ASA2. See Figure 1.

In order to test the possibility that the YAC EW7D11 carried the fad3 gene, the YAC was used to probe a cDNA library made from developing seeds of Canola (*Brassica napus* L.). Even though the YAC was isolated from Arabidopsis, the fact that Arabidopsis and *B. napus* are both members of the family Cruciferae led us to predict that the homologous genes from these two species would be sufficiently identical at the nucleotide sequence level so that the Arabidopsis gene would hybridize to the *B. napus* gene. We also assumed that, because it catalyzes a chemically similar reaction to the stearoyl-ACP desaturase, it would be expressed at similar moderately high levels in developing seeds (Shanklin and Somerville, 1991). Since EW7D11 contained only about 0.2% of the total genome, we expected it to contain only about 2 moderately abundantly expressed genes (i.e., genes in which the mRNA is between 0.1 and 0.01% of total mRNA).

DNA of YAC EW7D11 was isolated as follows: high molecular weight DNA was prepared from the yeast cells that contained the YAC EW7D11 as described above, and several preparative low-melt agarose CHEF gels were run in 1XTBC buffer (same as TBE except that CDTA was substituted for EDTA). The slices that contained the YAC were excised from the gels and pooled. Three slices were melted at 65°C and extracted with an equal volume of phenol saturated with TE. The aqueous phase was saved and reduced to 0.5 ml by repeated extractions with isobutyl alcohol. The remaining agarose was removed by several phenol extractions, followed by two chloroform-isoamyl alcohol extractions. The DNA was precipitated by adding 2 µg of linear acrylamide as a carrier plus 10 µl of 5M NaCl and 1.1 ml of ethanol, and incubating 20 min at 0 °C. The DNA pellet was recovered by centrifugation, washed in 70% ethanol, dried under vacuum and resuspended in 50 µl of distilled water. The DNA (50 ng) was radioactively labelled and used to probe a cDNA library in λgt11.

The nitrocellulose filters were processed as described in Sambrook et al (1989). Duplicate filters were used, and the films were exposed 5-7 days in order to obtain a good signal. From among 200,000 plaques screened in this way, 31 hybridized to EW7D11. Among these 31 clones, 17 were homologous to each other, as checked by cross hybridization in stringent conditions. The size of the inserts in the 17 clones was estimated and the clone with the largest cDNA was retained for further analysis. A small scale preparation of this phage was prepared using the lambdasorb method, and the insert was excised by restricting with EcoR1. This insert was ligated into a pBLUESCRIPT II vector linearized with EcoRI, and the ligation mixture was used to transform E. coli strain DH5α.

One of the recombinant clones was designated pBNDES3 (Figure 2), and retained for sequencing. The sequence was determined on both strands, using the sequenase enzyme, (US Biochemicals, Cleveland, OH) according to the instructions provided by the supplier. The nucleotide sequence of the insert in pBNDES3 is presented as Figure 3. The deduced amino acid sequence of the largest open reading frame in the nucleotide sequence is also shown in Figure 3.

Comparison of the deduced amino acid sequence of the 383 amino acid open reading frame in clone pBNDES3 against the known sequences in GenBank release 70 was performed using the FASTA program (Lipman and Pearson, 1985). This analysis revealed that the sequence from pBNDES3 had a region of significant homology to a previously characterized desaturase gene from the cyanobacterium Synechocystis (Figure 4). (Wada et al. 1990). This was considered suggestive evidence that the clone pBNDES3 encoded a desaturase which was probably the fad3 structural coding sequence product. This was subsequently confirmed by a genetic complementation experiment.

The cDNA was cloned into plant transformation vector pBI121 (Figure 5) under the control of the CaMV35S promoter to construct pTiDES3 (Figure 6). Plasmid pTiDES3 was introduced into an *Agrobacterium tumefaciens* strain which also carried an Ri plasmid and this was used to produce transgenic rooty tumors from both wild type Arabidopsis and the fad3 mutant. Transgenic tissue was selected for antibiotic resistance to confirm the presence of the pTiDES3. Fatty acid methyl esters were then prepared and examined by gas chromatography to determine the profile of fatty acids being produced in the tissue. The levels of linolenic acid increased, demonstrating that the cDNA on pTiDES3 can complement the fad3 mutation. These results, which are described in detail in Example 1 below, confirm the identity of the cDNA as encoding a linoleic acid desaturase.

The isolation of a plant structural coding sequence provides those skilled in the art with a tool for the manipulation of gene expression by the mechanism of antisense RNA. The technique of antisense RNA is based upon introduction of a chimeric gene which will produce an RNA transcript that is complementary to a target gene (reviewed in Bird and Ray, 1991). The resulting phenotype is a reduction in the gene product from the endogenous gene. The portion of the gene which is sufficient for achieving the antisense effect is variable in that numerous fragments or combinations thereof are likely to be effective. Various portions of the structural coding sequence of linoleic acid desaturase isolated either from cDNA or genomic clones are likely capable of reducing linolenic acid levels in plants by reduction in levels of linoleic acid desaturase levels. An example of using an antisense oriented linoleic acid desaturase structural coding sequence is set out in Example 2.

Polyadenylation Signal

The 3' non-translated region of the double stranded DNA molecule of the present invention contains a region that functions in plant cells to promote polyadenylation to the 3' end of the RNA sequence. Any such regions can be used within the scope of the present invention. Examples of suitable 3' regions are (1) the 3' transcribed, non-translated regions containing the polyadenylated signal of *Agrobacterium* tumor-inducing (Ti) plasmid genes, such as the nopaline synthase (NOS) gene, and (2) 3' regions of plant genes like the soybean storage protein genes and the small subunit of the ribulose-1,5-bisphosphate carboxylase (ssRUBISCO) gene. An example of a preferred 3' region is that from the NOS gene, described in greater detail in the examples below.

Plant Transformation/Regeneration

Any plant which can be transformed to contain the double-stranded DNA molecule of the present invention are included within the scope of this invention. Preferred plants which can be made to have increased or decreased linolenic acid content by practice of the present invention include, but are not limited to sunflower, safflower, cotton, corn, wheat, rice, peanut, canola/oilseed rape, barley, sorghum, soybean, flax, tomato, almond, cashew and walnut.

A double-stranded DNA molecule of the present invention containing the functional plant linoleic acid desaturase gene can be inserted into the genome of a plant by any suitable method. Suitable plant transformation vectors include those derived from a Ti plasmid of *Agrobacterium tumefaciens*, as well as those disclosed, e.g., by Herrera-Estrella (1983), Bevan (1984), Klee (1985) and EPO publication 120,516 (Schilperoort et al.). In addition to plant transformation vectors derived from the Ti or root-inducing (Ri) plasmids of *Agrobacterium*, alternative methods can be used to insert the DNA constructs of this invention into

plant cells. Such methods can involve, for example, the use of liposomes, electroporation, chemicals that increase free DNA uptake, free DNA delivery via microprojectile bombardment, and transformation using bacteria, viruses or pollen.

A plasmid expression vector, suitable for the expression of the linoleic acid desaturase gene in monocots is composed of the following: a promoter that is specific or enhanced for expression in the lipid storage tissues and a 3' polyadenylation sequence such as the nopaline synthase 3' sequence (NOS 3'; Fraley et al., 1983). This expression cassette may be assembled on high copy replicons suitable for the production of large quantities of DNA.

A particularly useful *Agrobacterium*-based plant transformation vector for use in transformation of dicotyledonous plants is plasmid vector pMON530 (Rogers, S.G., 1987). Plasmid pMON530 (see Figure 7) is a derivative of pMON505 prepared by transferring the 2.3 kb StuI-HindIII fragment of pMON316 (Rogers, S.G., 1987) into pMON526. Plasmid pMON526 is a simple derivative of pMON505 in which the SmaI site is removed by digestion with XmaI, treatment with Klenow polymerase and ligation. Plasmid pMON530 retains all the properties of pMON505 and the CaMV35S-NOS expression cassette and now contains a unique cleavage site for SmaI between the promoter and polyadenylation signal.

Vector pMON505 is a derivative of pMON200 (Rogers, S.G., 1987) in which the Ti plasmid homology region, LIH, has been replaced with a 3.8 kb HindIII to SmaI segment of the mini RK2 plasmid, pTJS75 (Schmidhauser & Helinski, 1985). This segment contains the RK2 origin of replication, oriV, and the origin of transfer, oriT, for conjugation into *Agrobacterium* using the tri-parental mating procedure (Horsch & Klee, 1986). Plasmid pMON505 retains all the important features of pMON200 including the synthetic multi-linker for insertion of desired DNA fragments,

the chimeric NOS/NPTII'/NOS gene for kanamycin resistance in plant cells, the spectinomycin/streptomycin resistance determinant for selection in *E. coli* and *A. tumefaciens*, an intact nopaline synthase gene for facile scoring of transformants and inheritance in progeny and a pBR322 origin of replication for ease in making large amounts of the vector in E. coli. Plasmid pMON505 contains a single T-DNA border derived from the right end of the pTiT37 nopaline-type T-DNA. Southern analyses have shown that plasmid pMON505 and any DNA that it carries are integrated into the plant genome, that is, the entire plasmid is the T-DNA that is inserted into the plant genome. One end of the integrated DNA is located between the right border sequence and the nopaline synthase gene and the other end is between the border sequence and the pBR322 sequences.

When adequate numbers of cells (or protoplasts) containing the linoleic acid desaturase gene are obtained, the cells (or protoplasts) are regenerated into whole plants. Choice of methodology for the regeneration step is not critical, with suitable protocols being available for hosts from *Leguminosae* (alfalfa, soybean, clover, etc.), *Umbelliferae* (carrot, celery, parsnip), *Cruciferae* (cabbage, radish, rapeseed, etc.), *Cucurbitaceae* (melons and cucumber), *Gramineae* (wheat, rice, corn, etc.), *Solanaceae* (potato, tobacco, tomato, peppers) and various floral crops. See, e.g., Ammirato (1984); Shimamoto, 1989; Fromm, 1990; Vasil and Vasil, 1990.

<u>Uses of Linoleic Acid Desaturase</u>

The present invention can be used for any modification (either increase, decrease, or mere change) of the oil content of a plant or plant tissue. Linolenic acid is an important constituent of several membranes in plant cells.

One preferred method is to modify the oil content of the plant to improve the plant's temperature sensitivity. For instance, plants deficient in linolenic acid display reduced fitness at low temperature (Hugly and

Somerville, 1992). Also, increased linoleic acid content in vegetative tissues has been implicated as a factor in freezing tolerance in higher plants (Steponkus et al., 1990 and references therein). In a preferred embodiment, expression of the linoleic acid desaturase structural coding sequence can result in the genetic modification of higher plants to achieve tolerance to low environmental temperatures. Transformation with pTiDES3 demonstrates that linolenic acid levels can be increased by expression of this gene in a constitutive manner. Chilling or freezing injury in crops may be overcome by expression of this gene in vegetative or reproductive tissues by employing an appropriate promoter.

Linolenic acid, a polyunsaturated fatty acid, is also extensively used in the paint and varnish industry in view of its rapid oxidation. Flax seed is a predominant source of this oil. Higher quantities of this fatty acid in rapeseed or soybean will provide opportunities for using vegetable oils from these sources as a replacement for linseed (flax) oil. Expression of a linoleic acid desaturase structural coding sequence in seed tissue can result in a higher proportion of linolenic acid in the storage oil.

Linolenic acid is further a precursor in the biosynthesis of jasmonic acid, an important plant growth regulator. Linolenic acid is converted to jasmonic acid by introduction of an oxygen to the carbon chain by a lipoxygenase, followed by dehydration, reduction, and several β-oxidations (Vick and Zimmerman, 1984). The activity of jasmonic acid has been measured in terms of induction of pathogen defense responses. By application of free linolenic acid to plants, plant pathogen defenses can also be induced (Farmer and Ryan, 1992). A model has been proposed to explain the ability of free linolenic acid to exhibit the effects associated with jasmonic acid (Farmer and Ryan, 1992). It is hypothesized that all of the enzymatic activities which are required for the conversion of linolenic acid to jasmonic acid are constitutively present in the cell and the rate limiting

step in the production of jasmonic acid is the availability of free linolenic acid. A likely route for the production of the free linolenic acid is by the activity of a lipase in the plasma membrane.

It further has been observed that exogenous jasmonic acid can more powerfully activate defense responses than can wounding. This suggests that wounds cannot generate enough free linolenic acid to support high level production of jasmonic acid. The activity of the lipase or the availability of appropriate substrate for the lipase may be rate limiting upon wounding. By increasing levels of available substrate, increasing linolenic acid levels in the plasma membrane, it should be possible to enhance a plant's ability to respond to pathogens by allowing for a higher production of jasmonic acid. Expression of a linoleic acid desaturase structural coding sequence can result in a higher molar percent linolenic acid in the plasma membrane of a plant cell therefore enhancing the jasmonic acid signaling pathway. It is our intent to evaluate plants containing high linolenic acid levels in root and foliar tissues for their pathogen resistance.

It is also undesirable to have significant levels of linolenic acid in cooking oils. Linolenic acid is unstable during cooking and is rapidly oxidized. The oxidized products impart rancidity to the finished product. Rapeseed or soybean oil containing less than about 3%, and preferably 2% or less of linolenic acid is ideal for use as a cooking oil. By expression of the antisense of the structural coding sequence for linoleic acid desaturase, it is possible to reduce the linolenic acid content of these oils.

All higher plants have linolenic acid and, therefore, contain genes for linoleic acid desaturases. Because of the many examples in which genes isolated from one plant species have been used to isolate the homologous genes from other plant species, it is apparent to any one skilled in the art, that the results presented here do not only pertain to the use of the *B.*

napus fad3 gene, or to the use of the gene to modify fatty acid composition in *B. napus*. Obviously, the linoleic acid desaturases from many organisms could be used to increase linolenic acid biosynthesis and accumulation in plants and enzymes from any other higher plant or algae can serve as sources for linoleic acid desaturase genes. For example, since a YAC containing the *Arabidopsis* gene was used to isolate the *B. napus* gene, it is apparent that the insert in pBNDES3 could be used as a probe of genomic libraries for isolation of the corresponding full length genes from other plant species. It is also likely that the information contained in the sequence of this gene will be useful to clone other lipid desaturases genes.

Expression of a linoleic acid desaturase in a sense orientation may also allow for the isolation of plants with reduced levels of linolenic acid. This could be accomplished by the mechanism of co-suppression (Bird and Ray, 1991). The molecular mechanism of co-suppression is at this time poorly understood but occurs when plants are transformed with a gene that is identical or highly homologous to an allele found in the plants genome. There are several examples where expression of a chimeric gene in plants can result in a reduction of the gene product from both the chimeric gene and the endogenous gene(s). Those skilled in the art will recognize that the resulting decrease in linolenic acid would be a direct result of expression of the linoleic acid desaturase structural coding sequence and would be correlated to the linoleic acid desaturase activity in the transformed plant.

Linolenic acid levels in plant cells can also be modified by isolating genes encoding transcription factors which interact with the upstream regulatory elements of the plant linoleic acid desaturase gene(s). Enhanced expression of these transcription factors in plant cells can effect the expression of the linoleic acid desaturase gene. Under these conditions, the increased or decreased linolenic acid content would also be caused by a corresponding increase or decrease in the activity of the linoleic acid

desaturase enzyme although the mechanism is different. Methods for the isolation of transcription factors have been described (Katagiri, 1989).

The following examples are provided to better elucidate the practice of the present invention and should not be interpreted in any way to limit the scope of the present invention. Those skilled in the art will recognize that various modifications, truncations, etc. can be made to the methods and genes described herein while not departing from the spirit and scope of the present invention.

Example 1

Expression of fad3 gene to increase linolenic acid

To verify the assumption that the cDNA insert in pBNDES3 encodes a linoleic acid desaturase, both wild type and fad3 mutation *Arabidopsis* were transformed to contain the cDNA insert. In order to express the linoleic acid desaturase structural coding sequence (hereafter referred to as the "fad3 gene") in plant cells, the plasmid pBNDES3 was digested with XhoI and the ends were filled in with the Klenow fragment of DNA polymerase (Sambrook et al 1989). The cDNA insert was subsequently excised by digestion with Sac1 and ligated into the Sac1 and Sma1 sites of the binary Ti plasmid vector pBI121 (Clontech Laboratories), thereby replacing the GUS reading frame. The ligation reaction was carried out in 20 µl for 12 h at 16 °C using 100 ng of both insert and vector, and one unit of T4 DNA ligase. The ligation mixture was used to transform competent DH5α *E. coli* cells (prepared by the calcium chloride method, according to Sambrook et al, 1989), and transformants were selected on L-broth plates that contained 50 µg/µl Kanamycin. Alkaline minipreparations of recombinant clones were analyzed for the correct restriction pattern. One of these plasmids, designated pTiDES3, was used for further experiments.

This plasmid was electroporated (according to Mersereau and Pazour, 1990) into *Agrobacterium tumefaciens* strain R1000 which carries an Ri plasmid. The transformed bacteria were selected on kanamycin LB plates for 2 days at 30 °C. DNA minipreparations of several recombinant bacteria were performed and analyzed as described above to verify the presence of the construct.

Young flowering stems of wild type and the fad3 mutant of Arabidopsis were sterilized for 30 min in 10% commercial bleach, 0.02% Triton X100, and 2-cm explants that contained the flowering stem were infected with R1000 (pTiDES3) This was performed by dipping the sectioned extremity in a drop of an overnight culture of the appropriate *Agrobacterium* that was grown from a single colony in LB medium supplemented with 50 ug/ml Kanamycin.

The infected stems were cultured for two days on solid MSO medium (Gibco MS salts plus Gamborg B5 vitamins, 3% sucrose and 0.8% agar). At this time the stem segments were transferred for 5 weeks to MS0 medium containing 200 μg/ml cefotaxime to kill the bacterium. After approximately two weeks, most of the stem explants had developed rooty tumors resulting from transfer of parts of the Ri plasmid into cells of the stem explants. In order to identify the rooty tumors which had also received the binary Ti plasmid pTiDES3, approximately 24 rooty tumors from each treatment were transferred to MSO medium containing 50 μg/ml of kanamycin to select for the growth of those roots which had been cotransformed with the binary Ti plasmid; the medium contained also 200 μg/ml of cefotaxime to inhibit bacterial growth. Following a further period of growth for 2 weeks, fatty acid methyl esters were prepared (as described above) from the roots for analysis by gas chromatography. The results of these analyses are presented in Table 2.

Table 2. Genotype

mol% Fatty acid	wildtype pBI121	fad 3 pBI121	wildtype pTiDES3	fad3 pTiDES3
16:0	22.0±2.9	21.2±1.6	21.1±0.9	21.3±2.3
16:1	2.5±0.7	1.6±0.8	2.0±0.1	1.5±0.2
18:0	2.3±1.9	2.3±1.9	1.9±0.2	1.6±0.4
18:1	3.8±1.3	5.9±2.6	7.7±2.0	9.1±2.0
18:2	37.3±3.7	62.2±5.9	15.7±11.7	24.4±14.9
18:3	31.9±4.5	6.7±0.7	51.3±10.9	42.1±15.5

Table 2 shows the fatty acid composition of transgenic roots. The transgenic roots resulting from infection of wild type or the fad3 mutant with *A. tumefaciens* R1000 carrying the vector (pBI121) or the plasmid pTiDES3 were grown in the presence of kanamycin (50 g/ml) for three weeks to identify the roots which had been cotransformed with one of these plasmids. The fatty acid composition of the roots was determined as previously described (Browse et al., 1986). The abbreviations used in Table 2 are as follows: 16:0, palmitic acid; 16:1, palmitoleic acid; 18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid; 18:3, linolenic acid. The values presented are the mean ± SD (n=12).

From these results it can be seen that the production of rooty tumors containing pBI121 on wild type *Arabidopsis* or the fad3 mutant had no effect on the fatty acid composition over non-pBI121 containing wild type *Arabidopsis* or fad3 mutant. By contrast, transformation of the fad3 mutant with the plasmid pTiDES3 resulted in large increases in the content of linolenic acid. In contrast to the linolenic acid content of 6.7 +/- 0.7% in the fad3 mutant transformed with pBI121, the presence of pTiDES3 resulted in accumulation of 42.1% of the fatty acids as linolenic acid. The increased content of linolenic acid was accompanied by a

decrease of corresponding magnitude in the content of linoleic acid. Thus, it is clear that the fad3 gene encodes a linoleic acid desaturase. Introduction of the fad3 gene into wild type tissues also resulted in significantly increased accumulation of linolenic acid and a corresponding decrease in linoleic acid (Table 2). Thus, it is apparent from these results that the linoleic acid content of plant tissues can be increased by high level expression of a linoleic acid desaturase. In the present embodiment, the fad3 gene was placed under transcriptional control of the constitutive high level CaMV 35S promoter carried on pBI121. The implication from these results is that expression from this promoter raised the level of expression of the fad3 gene to levels higher than are normally achieved by expression from the endogenous fad3 promoter. The results presented here indicate that the fad3 gene has significant utility in genetic modification of higher plants to elevate linolenic acid levels.

Example 2

Antisense expression of fad3 gene to decrease linolenic acid levels

In order to decrease the linoleic acid desaturase activity by genetic engineering methodology, the cDNA insert of pBNDES3 was cloned into plant expression cassettes in an antisense orientation. A 959bp BglII restriction fragment of pBNDES3 was used in the antisense expression vectors. The fragment is from 152 nucleotides downstream of the initiating methionine codon of the cDNA to a second BglII restriction site that is located near the C-terminus of the coding region. 189 nucleotides of the coding region are excluded from this fragment. Triple ligations were performed with the fad3 gene fragment to construct two separate plant expression cassettes.

A seed specific expression cassette was constructed by insertion of the BglII fragment of pBNDES3 in an antisense orientation behind the soybean promoter for the α' subunit of β-conglycinin (7S promoter). A

975bp HindIII to BglII fragment containing the 7S promoter derived from pMON529 was prepared by digesting with BglII for 30min at 37 °C followed by addition of Calf Intestinal Alkaline Phosphatase (CIAP) (Boehringer Mannheim). The reaction was allowed to proceed for 20min followed by purification of the linearized DNA using the GeneClean (Bio 101) purification system. The DNA was then digested with HindIII. A fragment derived from pMON999 containing the Nopaline synthase 3' region and the pUC vector backbone was prepared by digestion with BamHI and treatment with CIAP. The DNA was purified by the GeneClean procedure and digested with HindIII. The fragment of pBNDES3 was prepared by digestion with BglII. The three fragments were purified by agarose gel electrophoresis and the GeneClean procedure. 50 to 200ng of the purified fragments were ligated for one hour at room temperature followed by transformation into the *E. coli* strain JM101. Resulting transformant colonies were used for plasmid preparation and restriction digestion analysis. Double digestion with BglII and NcoI was used to screen for transformants containing the fad3 gene in an antisense orientation. One clone was designated as correct and named pMON13801.

A second expression cassette was constructed to allow for constitutive expression of the antisense message in plants. A fragment containing the enhanced 35S promoter was prepared from pMON999 by restriction digestion with HindIII and BglII followed by treatment with CIAP as above. The correct sized fragment was obtained by agarose gel electrophoresis and the GeneClean procedure. The BglII to HindIII vector fragment and the BglII fragment of pBNDES3 which were purified above were used in this construction. Ligation, transformation and screening of clones were as described above. One clone was designated as correct and named pMON13802.

In both pMON13801 and pMON13802, the promoter, fad3 gene and the Nos 3' region can be isolated on a NotI restriction fragment. These fragments can then be inserted into a unique NotI site of the vector pMON17227 to construct glyphosate selectable plant transformation vectors. The vector DNA is prepared by digestion with NotI followed by treatment with CIAP. The fad3 containing fragments are prepared by digestion with NotI, agarose gel electrophoresis and purification with GeneClean. Ligations are performed with approximately 100ng of vector and 200ng of insert DNA for 1.5 hours at room temperature. Following transformation into the E. coli strain LE392, transformants were screen by restriction digestion to identify clones containing the fad3 expression cassettes. Clones in which transcription from the fad3 cassette is in the same direction as transcription from the selectable marker were designated as correct and named pMON13804 (FMV/CP4/E9, 7S/anti fad3/NOS) (Figure 8) and pMON13805 (FMV/CP4/E9, E35S/anti fad3/NOS) (Figure 9).

In preparation for transforming canola cells, pMON13804 and pMON13805 were mated into Agrobacterium ABI by a triparental mating with the helper plasmid pRK2013.

Seeds from the plants produced by transformation were analyzed for alterations in fatty acid profile. Fatty acid methyl esters (FAMES) were prepared from seed tissue and analyzed by capillary gas chromatography (Browse et al, 1986). For initial screening of plants, six seeds were pooled together from an individual plant. The seeds were crushed and FAMES extracts were made. Control plants, plants transformed with the selectable marker only (pMON17227), were also analyzed using the identical procedure. From the initial screen on pooled seed samples, several lines were identified which displayed a decreased level of linolenic acid. Lines with decreased levels of linolenic acid were

reanalyzed by determining fatty acid profiles from individual seeds. Four to twenty individual seed were analyzed from candidate lines and from selected control plants. The results of the FAMES analysis is summarized in Figure 9.

Figure 9 shows the levels of fatty acids expressed in molar percent of twenty individual seed of the transgenic line 13804-51 as compared to control seed. Panel A discloses oleic acid, panel B discloses linoleic acid and panel C discloses linolenic acid.

The data in Figure 9 demonstrate that antisense expression of a linoleic acid desaturase has significantly altered the fatty acid profile of the resulting seed tissue. The percent of linolenic acid has been reduced to a little over 2% of the total fatty acid in the seed tissue. The percent of linoleic acid has been reduced slightly and surprisingly, the percent of oleic acid in the seed has been increased to approximately 70%. This demonstrates the applicability of utilizing the fad3 gene to manipulate the fatty acid profile of crop plants.

In order to demonstrate that the alteration in the fatty acid profile of the FAMES extracted from total seed tissue would be reflected in the seed oil fraction, triglycerides from seeds of fad3 antisense plants were characterized. Total lipid extracts were made by pooling ten seeds and grinding in 2ml of methanol:chloroform:water (4:2:1). The homogenate was allowed to stand for 20min and then debris was pelleted and discarded. To the supernatant 400µl of chloroform:methanol (2:1), 640µl of chloroform and 740µl of water was added and vortexed. Phases were separated by centrifugation and the chloroform phase was recovered and dried under nitrogen. Samples were resuspended in 100µl of chloroform and 10µl was applied to silica gel G thin layer chromatography plates for separation. Two identical plates were prepared with one being charred after development to allow for alignment and location of spots to be analyzed on

the other plate. Plates were developed three times in petroleum ether:diethyl ether:acetic acid (90:10:1). One plate was sprayed with 50% sulfuric acid and heated in an oven at 90°C to allow for detection of lipids. Triglyceride fractions were identified as comigrating on the plate with purchased lipid standards (Sigma Chemical Co, cat #178-13). The charred plate was aligned with the identical plate and the triglyceride fractions were scraped from the plate. The fatty acids were transesterified to produce FAMES extracts for GC analysis by the same procedure as above. The fatty acid profiles of the triglyceride fractions are shown in Table 3 and demonstrate that this fraction have decreased linolenic acid.

TABLE 3

Transgenic line	Mol% 18:1	18:2	18:3
17227-10	44	30	15.3
17227-493	65	17	6.9
13804-47	58	21	4.3
13804-50	67	20	2.8
13804-76	59	19	5.0
13804-117	62	21	4.0

Table 3 compares the fatty acid molar percentages of triglyceride fractions from control and transgenic lines. These above results provide clear evidence that the fad3 gene can be used to decrease the levels of linolenic acid in the storage oil of plants. The gene provides a tool for the manipulation of the fatty acid profile of seed storage oil to improve the products derived from the oil.

A surprising result of this Example 2 is the effect the antisense fad3 gene has on the oleic acid content. The precise mechanism by which

antisense expression of a gene exerts an effect on the activity of an endogenous gene is unclear but is obviously a function of the homology of the sense and antisense gene products. Based upon the above experimental result, it would not be unreasonable to predict that the portion of the fad3 gene antisense message used contained a certain degree of homology with the genes providing the activity of one or more oleate desaturases. Therefore, a further advantage of the above invention is that it is possible that expression of a linoleic acid desaturase antisense message may exert an effect on oleate desaturase activity.

The unexpected nature of the reduction in oleic acid desaturase activity from the antisense fad3 plants is most apparent when one compares the fatty acid profiles from the antisense plants and the fad3 mutant of *Arabidopsis*. The levels of linoleic acid in the fad3 mutant plants increased when linoleic acid desaturase activity was eliminated by mutation. This indicates that the activity of the oleate desaturase was not highly effected by the loss of linoleic acid desaturase activity or by the accumulation of linoleic acid. In the fad3 mutant of Arabidopsis the level of linoleic acid increased when the level of linolenic acid decreased. However, a different pattern occurred in the antisense fad3 plants. In plants which exhibit a decreased percent of linolenic acid there is no corresponding increase, and is often a decrease, in the percent of linoleic acid. There is an increase in the percent of oleate in the antisense fad3 plants. This would indicate that oleate desaturase activity is depressed in these plants. The effects on the fatty acid profile by the fad3 mutation and the fad3 antisense expression are not equivalent, indicating that antisense expression of a linoleic acid desaturase can depress an oleate desaturase activity in plants.

Example 3

Modification of linolenic acid levels in soybean

The isolation of the fad3 gene from *B. napus* provides a tool to those with ordinary skill in the art to isolate the corresponding gene or cDNA from other plant species. There are many examples in which genes from one plant species have been used to isolate the homologous genes from another plant species. One such plant which could be improved upon by the modification of the level of linolenic acid is soybean.

Soybean oil typically contains linolenic acid at a level of 7-9% of the fatty acid in the oil. This level is undesirable because it promotes instability upon heating and imparts rancidity to the finished product. The levels of linolenic acid can be lowered by the expression of the soybean fad3 gene or cDNA in an antisense orientation in the developing seed. The following example describes one method for the isolation of a fad3 cDNA from soybean. However, similar procedures could be followed to isolate a genomic clone which could also be used to decrease the level of linoleic acid desaturase activity by antisense expression of a portion or all of the gene.

The fad3 gene from *B.napus* is used as a probe to screen a cDNA library constructed from soybean mRNA. In order to isolate a cDNA to be used in decreasing linolenic acid in seed, the optimal tissue to use for the isolation of mRNA is developing seed. There is, however, flexibility in the choice of methods and vectors which can be used in the construction and analysis of cDNA libraries (Sambrook et al, 1989). Procedures for the construction of cDNA libraries are available from manufacturers of cloning materials or from laboratory handbooks such as Sambrook et.al, 1989. Once a suitable cDNA library has been constructed from soybean, all or a portion of the fad3 cDNA from *B.napus* is labeled and used as a probe of the library. DNA fragments can be labeled for radioactive or non-radioactive screening procedures. The library is screened under suitable stringency.

Conditions are dependent upon the degree of homology between the fad3 gene of *B. napus* and soybean. Probe positive clones are plaque purified by standard procedures and characterized by restriction enzyme mapping and DNA sequence analysis. Clones are concluded to be soybean fad3 based upon data obtained from the sequence analysis or by expression in plants.

The entire clone or a portion thereof is placed down stream of a promoter sequence in an antisense orientation. Suitable promoters include seed specific promoters, such as the 7S (β-conglycinin) α'-subunit promoter, or less tissue specific promoters, such as the CaMV 35S promoter. An appropriate 3' non-translated region is placed downstream of the antisense cDNA to allow for transcription termination and for the addition of polyadenylated nucleotides to the 3'end of the RNA sequence. This expression cassette is then combined with a selectable or scorable marker gene and soybean cells are transformed by free DNA delivery (Christou et al, 1990) or an Agrobacterium based method of plant transformation (Hinchee et al, 1988). Plants recovered are allowed to set seed and mature seed are used for the production of FAMES by the procedures outlined above. The FAMES extracts are analyzed by gas chromatography to identify plant lines with reduced levels of linolenic acid in the seed.

Alternatives to the above methods may include but are not limited to the use of degenerate oligonucleotides as probes to screen the library. Degenerate oligonucleotide probes would be most optimally designed by choosing short segments of the fad3 amino acid sequence where the degeneracy of the genetic code is limited or by choosing sequences which appear to be highly conserved between the fad3 gene of *B. napus* and other known linoleic acid desaturases, such as the desaturase from the cyanobacterium *Synechocystis*. The oligonucleotides could be labeled and used to probe a soybean cDNA library. Alternatively, degenerate

oligonucleotides could be used as primers for the isolation of a portion or all of the soybean cDNA by PCR amplification.

Similar procedures could be used to isolate the homologous genes from other plant species. Another preferred plant species which could be improved upon by the modification of the level of linolenic acid is flax. Flax oil typically contains linolenic acid at a level of 45-65% of the fatty acid in the oil. This level is undesirable because it promotes instability upon heating and imparts rancidity to the finished product.

Example 4

Sense expression of fad3 to obtain reduced levels of linolenic acid

The cloning of the fad3 gene also provides a tool to decrease the levels of linolenic acid via the mechanism of co-suppression. The molecular mechanism of co-suppression occurs when plants are transformed with a gene that is identical or highly homologous to an allele found in the plants genome (Bird and Ray, 1991). There are several examples where expression of a chimeric gene in plants can result in a reduction of the gene product from both the chimeric gene and the endogenous gene(s). Therefore the fad3 gene product of *B. napus* may be reduced by transformation of *B. napus* with all or a portion of the fad3 cDNA which has been isolated. The resulting plant has reduced linoleic acid desaturase activity in tissues where the chimeric gene is expressed. The phenotype of reducing the linoleic acid desaturase activity is a reduction in the levels of linolenic acid. The mechanism of co-suppression could be applied to any plant species from which the fad3 gene is cloned and the plant species is transformed with fad3 in a sense orientation.

In order to reduce levels of linolenic acid by the mechanism of co-suppression, a plant transformation construct is assembled with the fad3 gene or cDNA in a sense orientation. The entire clone or a portion thereof is placed downstream of a promoter sequence in a sense orientation. Suitable

promoters include seed specific promoters, such as the 7S (β-conglycinin) α'-subunit promoter, or less tissue specific promoters, such as the CaMV 35S promoter. An appropriate 3' non-translated region is placed downstream of the fad3 gene to allow for transcription termination and for the addition of polyadenylated nucleotides to the 3' end of the RNA sequence. This expression cassette is then combined with a selectable marker gene and *B. napus* cells are transformed by an *Agrobacterium* based method of plant transformation. Plants recovered are allowed to set seed and mature seed are used for the production of FAMES which are analyzed by gas chromatography to identify plant lines with reduced levels of linolenic acid in the seed.

Example 5

Isolation of a chloroplast delta 15 desaturase from *Arabidopsis*

A fragment of 959bp was excised from the fad3 cDNA insert using the restriction endonuclease BglII, and labeled radioactively according to Feinberg and Vogelstein (1983). This fragment was used to probe a cDNA library from *Arabidopsis* thaliana as described above (Example 1) except that the hybridization temperature was 52° C. Several cDNA clones were positive, and one of them (pVA1) was further characterized. Its deduced amino acid sequence exhibited a strong homology with fad3 except at the N-terminus. The cDNA insert was placed under the control of the 35S promoter in the Ti vector pBI121, and the resulting construct, pBIVA12 was electroporated into Agrobacterium (C58 pGV3101). The bacterium was used to transform the Arabidopsis mutant fadD. For transformation, plants were grown at 22° C with a light intensity of 100/μE/cm^{-2}, until bolting (approximately 2 and 1/2 weeks). The stems (1mm-10mm long) were removed and the plants were inoculated with a drop of an overnight culture of the bacterium. The same operation was repeated 7 days afterwards.

The plants were then allowed to set seeds. The seeds were plated (2500 seeds per 150mm petri dish) on MSO plates that contained 50μg/ml kanamycin to select for plants that had integrated the construct. One transformant plant was obtained, and the fatty acids from its leaves were analyzed by gas chromatography (Table 4). The results obtained show that the pBIVA12 construct is able to reestablish the levels of linolenic and hexadecatrienoic acids in the fadD mutant at a level equal to or superior to the wild type. This demonstrates that pVA12 encodes the fadD gene.

TABLE 4

fatty acid	fadD	WT	FadD pBIVA12
16:0	13.0	14.0	14.9
16:1	4.9	4.3	4.2
16:2	8.7	0.5	0.3
16:3	3.0	13.2	9.5
18:1	3.3	2.3	1.2
18:2	36.4	10.9	5.8
18:3	30.8	54.6	63.7

Table 4 shows the complementation of the fadD mutant. Fatty acids were extracted from leaves of *Arabidopsis* according to Browse et al (1986) and were quantified (mol%) by gas chromatography. WT stands for the Columbia wild type.

Example 6

Isolation of a second chloroplast delta 15 desaturase from *Arabidopsis*

A fragment of 959 bp was excised from the cDNA insert using the restriction endonuclease BglII, and labelled radioactively according to Feinberg and Vogelstein (1983). This fragment was used to probe a cDNA library from *Arabidopsis*, exactly as described above (Example 5). Among the several positive clones obtained, the cDNA pVA34 was further characterized. Its deduced amino acid sequence exhibited 71.8% and 79.5% homology with fad3 and fadD, respectively. The N-terminus resembled a chloroplast transit peptide, meaning that this protein is likely to be localized to the chloroplast. The strong homology with fad3 and fadD suggests that the protein is also a delta 15 desaturase. Aside from fad3 and fadD, the only locus known to control delta 15 desaturation is the fadE locus, which controls a temperature-induced delta 15 desaturase. Therefore, it is likely that the cDNA contained within the clone pVA34 corresponds to the fadE locus.

Example 7

Linoleic desaturase homology to plant oleic desaturases

The linoleic desaturase genes are the first plant desaturases isolated whose proteins enzymatically perform the desaturation of an unsaturated fatty acid precursor. The reaction that linoleic desaturase performs and the cofactors it uses are likely to be very similar for the oleic desaturase reaction. Given the similar reactions, similar substrates and probably similar cofactors, it is likely that the oleic desaturase genes and proteins have homology to the linoleic desaturase genes and proteins. That the genes share homology is supported by the finding that antisense expression of the linoleic acid desaturase message results in higher oleic acids levels, which experimentally indicates homology between the linoleic and oleic desaturases. These factors indicate that the linoleic desaturase

protein and nucleic acid sequences provide useful information for isolating other lipid desaturase genes, particularly oleic desaturase genes.

a. Identification of unknown cDNA sequences in databases.

Random cDNA sequencing generates a large number of sequenced clones but provides no information about the function of the encoded proteins. Homology to known proteins is the quickest method for identifying the protein function encoded in the sequenced cDNA. However, homology searches are informative only when a homology with a previously characterized protein are found. A cDNA sequence that is not homologous to any known protein remains in the unknown function category. Thus the results functionally identifying the linoleic desaturases by sequence and by their ability to complement mutations in plant desaturase genes now provides a method for identifying the function and identity of random cDNA clones by their homology to the linoleic desaturases. Additionally oleic desaturases are identified by their homology with linoleic desaturases.

A TFASTA search of the GenBank and EMBL public data bases for genes encoding proteins homologous to the protein sequence of the linoleic desaturase fad3 has identified both linoleic desaturases and a second class of plant lipid desaturases likely to be oleic desaturases. In particular, sequences found in GenBank and EMBL and identified as T04093 and T12950 show significant homology to linoleic desaturases but show less homology than other linoleic desaturases. These sequences have 30% homology to fad3 and 56% similarity to fad3 linoleic desaturase (TABLE 5). The full length clone of these cDNAs is obtained by standard methods and is inserted into plant gene expression and transformation vectors and transformed into fad2 Arabidopsis mutants to confirm the identity of the oleic desaturase by genetic complemention as was described in the example with linoleic desaturase.

b. <u>Isolation of a oleic desaturase cDNA.</u>

The protein sequence of plant linoleic desaturases can be used to isolate oleic desaturases. The conserved regions between the linoleic desaturases and the DesA oleic desaturase are functionally important and are conserved in the plant oleic desaturase proteins as well. These conserved amino acid sequences provide a method of isolating plant oleic desaturases. There are several regions of the linoleic desaturase fad3 that are conserved in fadD, fadE and DesA. The consensus amino acid sequence is shown in Table 6, with the amino acids identical in all four proteins shown in capital letters. As described below, oligonucleotides designed to encode the amino acids sequences in the conserved regions are used to identify and isolate plant oleic desaturases.

c. <u>Isolation of the fadC (fad6) Gene from *Arabidopsis thaliana*</u>

The fadC gene (also referred to as fad6) encodes a chloroplastic omega-6 desaturase.

The deduced amino acid sequences of the fad3 gene from *Brassica napus* and the fadD and fadE genes from *Arabidopsis thaliana* were compared with the DesA gene from *Synechocystis* (*Nature*, **347**:200, 1990). The sequence GHDCGH was determined to represent the most highly conserved region of these proteins. Consequently, a degenerate oligomer was designed that contains all the possible condons for the sequence GHDCGH. This oligomer has the following sequence: GGNCAYGAYTGYGGNCA.

An *Arabidopsis thaliana* cDNA phage library obtained from the laboratory of Dr. Ron Davis (*PNAS*, **88**: 1731-1735) was used to screen for desaturase genes. This library was made using material from all above ground plant parts.

Approximately 120,000 phage from the library were plated onto three plates and hybondN+ was then used to prepare three filters from each plate (*Molecular Cloning - A Laboratory Manual*, 2nd Edition. Eds. J. Sambrook, E. F. Fritsch, and T. Maniatis, Cold Spring Harbor Laboratory

Press, Cold Spring Harbor, New York 1989, hereafter "Sambrook"). Two filters from each plate were probed using the degenerate consensus oligomer which had been end-labelled with (32)P using T4 polynucleotide kinase. The hybridizations were performed in a solution that contained high amounts of tetramethylammonium chloride in order to minimize differences in the melting temperatures of the oligomers that together comprise the degenerate consensus oligomer. The hybridization solution had the following composition: 3 M tetramethylammonium chloride, 10 mM sodium phosphate pH 6.8, 1.25 mM EDTA, 0.5% SDS, 0.5% milk. Hybridization was carried out overnight at a temperature of 44ºC. Filters were then washed four times, 20 minutes each time, with 6 x SSC + 0.15% SDS at room temperature. Filters were then washed one time, for 30 minutes, with 4 x SSC + 0.1% SDS at room temperature. The filters were then exposed to film for two days.

The third set of filters that were made from each phage-containing plate were probed using DNA sequences from the three *Arabidopsis* desaturase genes that had already been identified: fad3, fadD and fadE. The fad3, fadD and fadE genes were labelled with (32)P and hybridized to the third set of phage filters in the following hybridization solution: 0.2 M NaCl, 20mM sodium phosphate pH 7.7, 2mM EDTA, 1% SDS, 0.5% milk, 10% dextran sulfate, 0.1% sodium pyrophosphate. Hybridization was carried out overnight at 65ºC. Filters were washed four times, 30 minutes per time, in 2 x SSC + 0.15% SD at room temperature and then for 45 minutes with 1 x SSC + 0.1% SDS at 65º C. The filters were then exposed to film for approximately two hours.

The two sets of filters that were probed with the degenerate consensus oligomer showed about 60 positive phage per plate (or about 180 total positive phage). Results from the third set of filters that were probed with the fad3, fadD and fadE genes indicated that only a small percentage

of the phage that hybridized to the consensus of oligomer contained the fad3, fadD or fadE genes.

Seventy-six of the phage that hybridized to the consensus oligomer, but not to the fad3, fadD or fadE genes, were plaque purified. The purified phage were then spotted onto bacteria growing on solid media on plates and allowed to form plaques. Several duplicate filters were then made of these plates (Sambrook). One of these filters was probed with the consensus oligomer, as described above. A second filter was probed with a mixture of the *Arabidopsis thaliana* fad3, fadD and fadE genes, as described above.

In order to determine which of the 76 phage contained the same cDNA inserts as which other phage, some of the filters were probed with cDNA inserts from some of the phage. In order to perform this experiment, the cDNA inserts from most of the phage were isolated by using oligomers that bound to DNA flanking the cDNA cloning site in the phage vector to isolate the cDNA sequences using the polymerase chain reaction (PCR). These cDNA sequences were labelled with (32)P (random hexamer labelling) and hybridized to the filters using the following hybridization solution: 30% formamide, 0.2M NaCl, 20mM sodium phosphate pH 7.7, 2mM EDTA, 1% SDS, 0.5% milk, 0.1% sodium pyrophosphate. The hybridizations were carried out for 14 hours at 65ºC. The filters were washed four times 15 minutes per wash, with 2 x SSC + 0.15% SDS at room temperature and were then exposed to film.

The combination of the high formamide concentration in the hybridization solution and the high hybridization temperature meant that only DNA sequences that were virtually identical would hybridize, allowing us to distinguish between nearly identical sequences. Several rounds of hybridizations using cDNA inserts from different phage were carried out until it had been determined which phage contained the same, or at least

extremely similar, cDNA inserts. On the basis of these experiments, we determined that all of the 76 phage contained one of four cDNA inserts. Sequence data was obtained from each of these four cDNAs. None of these cDNAs was found to be homologous to known desaturase genes, and so we feel that none of these four cDNAs is likely to encode a desaturase.

Since the number of phage that hybridized to the consensus oligomer was quite high (about 180 phage hybridized in the initial screen described above), we were not able to analyze all of the positive phage in the initial experiments. So, an attempt was made to identify phage that hybridized to the consensus oligomer but that did not contain the fad3, fadD of fadE genes or one of the four non-desaturase encoding clones that were identified in the first screen. In order to do this, between 500,000 and 1,000,000 phage from the library described above were plated onto 10 plates. Three filters were made from each plate (Sambrook). Two of these three sets of filters were then hybridized with (32) P labelled consensus oligomer as described above except that hybridization was carried out at 42ºC instead of at 44ºC. The third set of filters were hybridized with (32)P labelled DNA from the *Arabidopsis* fad3, fadD and fadE genes together with DNA from each of the four cDNA's identified in the first round of screening as hybridizing to the consensus oligomer but not encoding desaturases. This third set of filters were hybridized in: 30% formamide, 0.2 M NaCl, 20mM sodium phosphate pH 7.7, 2mM EDTA, 1% SDA, 0.5% milk, 0.1% sodium pyrophosphate at 65ºC. All three sets of filters were hybridized for 12 hours and then washed several times with 2 x SSC + 0.15% SDS at room temperature. The filters were then exposed to film.

Approximately 200 phage from each plate hybridized to the consensus oligomer. 50-60% of these phage also hybridized to fad3, fadD, fadE or to one of the four clones identified in the first screen. About 58 phage that hybridized to the consensus oligomer, but not to fad3, fadD,

fadE or one of the four previously identified clones, were plaque purified. The purified phage were then spotted onto a bacterial lawn growing on solid media on a petri plate and the phage were allowed to form plaques. Several filters were prepared from these plates and hybridized with (32)P labelled cDNA inserts from various of the newly purified phage, as described above. In this manner, all of the phage identified in this second round of screening were found to contain one of eight different cDNA inserts.

Sequence data was obtained from each of the eight cDNA's. One of the cDNA's, which was contained within only one of the phage, was found to have some sequence similarity of a known desaturase gene from cyanobacteria, the DesA gene. Further sequence information was obtained for this clone. This additional sequence showed very significant sequence similarity to the DesA gene, confirming that the clone contained a desaturase gene. The remainder of the cDNA contained within the clone was sequenced and compared with the sequences of other known desaturases. The new desaturase was 53.0% identical to DesA at the nucleotide level and 43.9%, 45.6% and 47.0% identical to *B. napus* fad3, *Arabidopsis* fadD and *Arabidopsis* fadE, respectively. As the gene contained within the clone was significantly more similar in sequence to the DesA gene (which is a delta-12 desaturase) than to fad3, fadD or fadE (which are omega-3 desaturases), the new desaturase was expected to be a delta-12 (= omega-6) desaturase.

The additional sequence data also indicated that this new desaturase gene contains a region that has only a one base pair mismatch to the desaturase consensus sequence described above. This mismatch means that the new desaturase has the sequence GHDCAH instead of GHDCGH.

A clone containing a full length cDNA for this gene was isolated and completely sequenced. This full length cDNA was sub-cloned

into the plant transformation vector pBII121 such that the gene is transcribed under the control of the 35S promoter. This construct was then used to complement the phenotype of a fadC mutant (*Plant Phys.* **90**: 522-529, 1989) of *Arabidopsis thaliana*, indicating that the gene encodes a chloroplastic omega-6 desaturase.

d. Proposed isolation of fad2

The most highly conserved peptide regions in the linoleic desaturases and the DesA desaturase were chosen as regions likely to be conserved in oleic desaturases. These 8 conserved regions are shown in TABLE 6. These regions were chosen on the following basis: These regions have areas highly conserved between the 3 linoleic desaturases and DesA, with at least 4 identical amino acids over a 10 amino acid span. Once a region was identified as conserved, the fad3 linoleic desaturase sequence was used as the amino acid sequence for the source of homology to identify oleic desaturases. This is because both fad3 and the non-plastid oleic desaturases are thought to be localized to the endoplasmic reticulum and are most likely to contain similar amino acid sequences.

Several peptide endpoints in each conserved area were chosen as the basis to subsequently design oligonucleotide probes for identifying the oleic desaturase gene. The peptide endpoints were chosen to be between 5 and 9 amino acids in length. The peptide end points were chosen to end on the conserved (identical) amino acids, and most often to begin on conserved amino acids. The rationale is that within the larger conserved area, some amino acid portions are more highly conserved than others, that 15 to 27 (5 to 9 amino acids) nucleotides is a good primer size for PCR, and that for PCR it is important that the 3' end of the primer matches the target, with the conserved (identical) amino acids the most likely to be present in the oleic desaturases. These 28 "oleic desaturase" peptide targets (Table 6) are the basis oligonucleotides that are designed for

hybridizing to the oleic desaturase cDNA sequences to identify and isolate the oleic desaturase cDNA clone.

Several possible methods for designing oligonucleotides and isolating the genes encoding the target peptide regions are known. For a discussion of designing degenerate oligonucleotides see *PCR Protocols - A Guide to Methods and Applications,* Eds M. A. Innis, D. H. Gelfand, J J Sninsky and T. J. White, Academic Press, San Diego, California, 1990; and Sanxxxxx The two most common screening methods using the oligonucleotides are screening cDNA libraries and PCR amplification of specific cDNAs. Gene probes from fad3, fadD and fadE are used under stringent hybridization conditions to identify these cDNAs and discard them in the screen for oleic desaturase cDNA clones. The method for using degenerate oligonucleotides to screen a cDNA library has been described in the example above demonstrating the isolation of the fadC oleic desaturase gene. An immature plant seed active in oil biosynthesis, generally 2 to 5 weeks after pollination, preferably about 3 to 4 weeks after pollination, of a plant such as Arabidopsis or canola is used as the source of mRNA for making cDNA. First strand cDNA is made from the isolated mRNA and hybridized under stringent conditions in solution to an excess of biotinylated fad3, fadD and fadE cloned cDNAs. The hybrids and biotinylated nucleic acids are removed with strepavidin and a second round of substraction is done to remove any remaining fad3, fadD and fadE sequences. The cDNA remaining in solution is used for PCR reactions. (For 5' RACE, see below, a polyA tail is added to the first strand cDNA 3' end).

A method that can readily evaluate a number of degenerate oligonucleotides probes is degenerate PCR (See chapters by Compton and by Lee and Caskey in *PCR Protocols*, cited above). In this method a degenerate set of oligonucleotides encompassing all the possible codon choices for the target peptide is synthesized (such degenerate

targets (Table 6) are the basis oligonucleotides that are designed for hybridizing to the oleic desaturase cDNA sequences to identify and isolate the oleic desaturase cDNA clone.

Several possible methods for designing oligonucleotides and isolating the genes encoding the target peptide regions are known. * done in two oligo pools

Table 7 shows the 28 peptide targets from the eight conserved regions and the 30 degenerate oligonucleotides derived from the peptide sequences. The degeneracy was kept to less than 516 fold, for those instances where more degeneracy occurred, by the use of deoxyinosine (Sambrook et al.) and by not including the last nucleotide in the last codon, and in two cases by the use of two subpools. Table 8 shows the amount of degeneracy for each designed oligonucleotide sequence and the amount of homology of the oligonucleotides to the *Arabidopsis* oleic desaturase fad2 (Accession No. L26296). Also shown in Table 8 is the percent homology in the last 10 nucleotides on the 3' end of each primer, since this region is most important for annealing and elongation under PCR conditions. It is expected that both 10 of 10 and 9 of 10 homology matches, and probably 8 of 10 homology matches in the 3' primer regions will serve as efficient PCR primers. Note that for oligonucleotide sets 1a through 5b (for 3' RACE) the strand direction is the same as the mRNA while for oligonucleotide sets 6a through 8e (for 5' RACE) the direction is opposite of the mRNA. Four oligonucleotides have a 10 of 10 match in the 3' position, 6 oligonucleotides match 9 of 10 in the 3' position and 12 match in 8 of 10 nucleotides in the 3' position. Oligonucleotides corresponding to peptides 2a, 2c, 2d, 3c, 4b, 4d, 6b, 7c, 8c, and 8d show 90% or greater homology in their last 10 nucleotides and anneal to the oleic desaturase gene and serve as primers to this gene. This demonstrates the validity of using the conserved regions of the plant linoleic desaturases and DesA to identify and isolate plant oleic desaturases.

The first round of PCR products are subjected to two rounds of subtraction using biotinylated fad3, fadD and fadE cloned cDNA to remove any hybridizing fad3, fadD and fadE sequences with strepavidin. This subtracted DNA is greatly enriched for fad2 sequences and depleted of fad3, fadD and fadE sequences. These 30 samples are run on agarose gels,

blotted and hybridized with pools of probe from the 30 samples. Pools of 5 of each of the 30 PCR samples are labeled with random primers and hybridized to the blots of the 30 samples, for a total of 6 blots hybridized with 6 pools of 5 probes. Additionally, a pool of fad3, fadD and fadE probe is hybridized to a duplicate blot. Bands that do not hybridize strongly to fad3, fadD and fadE but do cross hybridize to probe made from a different sample are strong candidates for fad2 as fad2 is likely to be the only DNA amplified in two or more independent PCR reactions. Positively hybridizing lanes identify samples to amplify by PCR using the same primers as in the initial reaction for 5 to10 cycles and the PCR products are cloned into plasmid vectors. The same probe that recognized the sample on the blot is used to screen the library and identify the hybridizing clone. Positive clones are sequenced and identified as fad2 clones by their homology but non-identity with fad3, and further characterized as described below.

In the event that fad2 sequences are not sufficiently enriched in one round of PCR to be identified, a second round of PCR is performed. If the lack of detection is due to insufficient amplification of fad2, then another round of PCR using the same primers on the subtracted PCR first round samples and the same simple screen as described above will identify fad2. If there are too many competing non-specific reactions then a second round of PCR using a different primer combination will remove non-specific amplifications and enrich for fad2. To further enrich for fad2 sequences each of the initial 30 PCR samples (one for each oligonucleotide in Table 7) after subtraction as described above, is subjected to a second round of PCR reactions using a different primer combination than the first reaction. One of the primers would be the same degenerate oligonucleotide primer as in the first PCR reaction. The second primer would now be from one of the 30 primers in Table 7 from the opposite class, ie, primers from 1a to 5b form matched sets with primers from 6a to 8e (primers 1a to 5b are in the sense

direction while primers 6a to 8e are in the antisense direction). For example, if oligonucleotide 1a was used initially, it is used again as one of the two primers and the second primer is each of the 6a to 8e oligonucleotides for a total of 11 separate PCR reactions. In total the 30 initial reactions result in 418 second cycle PCR reactions, a number easily handled by PCR technology. Essentially this second PCR cycle accomplishes a "nested" or sequential PCR reaction step after removing all the linoleic desaturases by the subtraction step. This increases the amplification as well as the specificity. Identification of samples containing fad2 are performed similarly as described above, with the 418 samples dot blotted onto 22 filters and probed with 21 pools of 20 samples and with a pool of fad3, fadD and fadE. Again, any sample that cross hybridizes with an independent probe sample and does not hybridize to fad3, fadD and fadE is a candidate for containing fad2 in the sample. If fad3, fadD and fadE hybridization is still present, another biotinylation/stepavidin subtraction should remove it. Positively hybridizing samples are run on gels, the band identified by hybridization and isolated for cloning. This second set of PCR reactions produces PCR products of a predictable size since both primers are within the coding region where little variation in size is expected. Thus the presence of a band of the expected size on a gel is diagnostic of fad2, particularly if hybridization of a blot of such a gel with a fad3, fadD and fadE probe indicates the band is not due to fad3, fadD and fadE contamination. After cloning the inserts in E. coli, the resulting plasmids containing the insert are identified by hybridization. They are sequenced and identified as oleic desaturases by their homology but non-identity with the linoleic desaturases, as in the examples described previously. The full length clone of these cDNAs is obtained by standard methods and inserted into plant gene expression and transformation vectors and transformed into *Arabidopsis* fad2 mutants to confirm the identity of the oleic

desaturase by genetic complemention as was described in the example with linoleic desaturase.

Thus in this approach to isolating the plant oleic desaturases, the total number of peptide regions is 8, comprised of 28 smaller peptide targets. This leads to set of 30 degenerate oligonucleotides, that are used in the PCR amplification and screening of the PCR products. Subtraction of interfering fad3, fadD and fadE sequences is used at several points. If necessary a second round of PCR reactions with paired internal primers gives extra amplification and specificity. This approach identifies the plant oleic desaturases, and the sequence of the isolated clones should confirm their identity by their homology to the plant linoleic desaturases as described. Thus a defined approach to isolating the plant oleic desaturases from the information about linoleic desaturases is presented here. The example given here is for Arabidopsis or canola oleic desaturases, but the approach is not limited to those plants as the oleic desaturases are probably highly conserved in most plants. Thus once one plant oleic desaturase is isolated, the sequence information is used to isolate the genes from other plant species by direct hybridization or by an approach similar to the one described here.

SEQUENCE LISTIN

(1) GENERAL INFORMATION:

(i) APPLICANT:
(A) NAME: Monsanto Company
(B) STREET: 800 North Lindbergh Boulevard
(C) CITY: St. Louis
(D) STATE: Missouri
(E) COUNTRY: United States of America
(F) POSTAL CODE (ZIP): 63167
(G) TELEPHONE: (314)694-3131
(H) TELEFAX: (314)694-5435

(ii) TITLE OF INVENTION: Altered Linolenic and Linoleic Acid Content in Plants

(iii) NUMBER OF SEQUENCES: 72

(iv) COMPUTER READABLE FORM:
(A) MEDIUM TYPE: Floppy disk
(B) COMPUTER: IBM PC compatible
(C) OPERATING SYSTEM: PC-DOS/MS-DOS
(D) SOFTWARE: PatentIn Release #1.0, Version #1.25 (EPO)

(vi) PRIOR APPLICATION DATA:
(A) APPLICATION NUMBER: US 08/156551
(B) FILING DATE: 22-NOV-1993

(vi) PRIOR APPLICATION DATA:
(A) APPLICATION NUMBER: US 08/014431
(B) FILING DATE: 05-FEB-1993

(2) INFORMATION FOR SEQ ID NO:1:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 1353 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: double
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: cDNA

(ix) FEATURE:
(A) NAME/KEY: CDS
(B) LOCATION: 87..1238

(2) INFORMATION FOR SEQ ID NO:34:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 23 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:34:

ARNCCNCCNC KNARRTARCT CCA 23

(2) INFORMATION FOR SEQ ID NO:35:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 23 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:35:

ARNCCNCCNC KNARRTANGA CCA 23

(2) INFORMATION FOR SEQ ID NO:36:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 20 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:36:

RTCNCKRTCD ATNGTNGTNA 20

(2) INFORMATION FOR SEQ ID NO:37:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 18 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:37:

RTARTCNCKR TCDATNGT 18

(2) INFORMATION FOR SEQ ID NO:38:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 18 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:38:

RTGNGTNCCD ATRTCRTG 18

(2) INFORMATION FOR SEQ ID NO:39:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 18 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:39:

NARRTGRTGD ATNACRTG 18

(2) INFORMATION FOR SEQ ID NO:40:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 21 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:40:

DATYTGNGGR AANARRTGRT G 21

(2) INFORMATION FOR SEQ ID NO:41:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 20 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:41:

GGDATYTGNG GRAANARRTG 20

(2) INFORMATION FOR SEQ ID NO:42:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 23 base pairs
(B) TYPE: nucleic acid
(C) STRANDEDNESS: single
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: DNA (synthetic)

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:42:

RTARTGNGGD ATYTGNGGRA ANA 23

(2) INFORMATION FOR SEQ ID NO:43:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 7 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:43:

Asp Ile Arg Ala Ala Ile Pro
1 5

(2) INFORMATION FOR SEQ ID NO:44:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 6 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:44:

Ala Ile Pro Lys His Cys
1 5

(2) INFORMATION FOR SEQ ID NO:45:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 6 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:45:

Lys His Cys Trp Val Lys
1 5

(2) INFORMATION FOR SEQ ID NO:46:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 8 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:46:

Trp Phe Leu Trp Pro Leu Tyr Trp
1 5

(2) INFORMATION FOR SEQ ID NO:47:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 5 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:47:

Trp Phe Leu Trp Pro
1 5

(2) INFORMATION FOR SEQ ID NO:48:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 5 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:48:

Trp Pro Leu Tyr Trp
1 5

(2) INFORMATION FOR SEQ ID NO:49:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 6 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:49:

Trp Val Ala Gln Gly Thr
1 5

(2) INFORMATION FOR SEQ ID NO:50:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 6 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

(xi) SEQUENCE DESCRIPTION: SEQ ID NO:50:

Trp Val Ala Gln Gly Thr
1 5

(2) INFORMATION FOR SEQ ID NO:51:

(i) SEQUENCE CHARACTERISTICS:
(A) LENGTH: 6 amino acids
(B) TYPE: amino acid
(D) TOPOLOGY: linear

(ii) MOLECULE TYPE: peptide

Claims:

1. A genetically transformed plant which has an elevated linolenic acid content comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

2. The plant of claim 1 in which the linoleic acid desaturase activity is from plants.

3. The plant of claim 1 in which the linoleic acid desaturase activity is from fungi, algae or bacteria.

4. The plant of claim 1 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:1.

5. The plant of claim 1 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:9.

6. The plant of claim 1 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:11.

7. The plant of claim 1 in which the promoter of (i) is an endogenous plant linoleic acid desaturase promoter.

8. A genetically transformed plant which has a reduced linolenic acid content, comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

9. The plant of claim 8 in which the linoleic acid desaturase enzyme is from plants.

10. The plant of claim 8 in which the linoleic acid desaturase enzyme is from fungi, algae or bacteria.

11. The plant of claim 8 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:1.

12. The plant of claim 8 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:9.

13. The plant of claim 8 in which the structural coding sequence of (ii) is taken from SEQ. 8 ID NO:11.

14. The plant of claim 8 in which the promoter of (i) is an endogenous plant linoleic acid desaturase promoter.

15. A genetically transformed plant which has an improved resistance to low temperatures comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

16. A genetically transformed plant which has an elevated ability to respond to pathogens, comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

17. A seed produced from genetically transformed plant where said seed has an linolenic acid content suitable for use as a source of linolenic acid, said plant comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

18.The seed of claim 17 where said plant is selected from the group consisting of soybean and rapeseed.

19. A genetically transformed plant which has a linolenic acid content of less than about 3%, said plant comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

20. A genetically transformed plant which has an increased oleic acid content, comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a oleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

21. A genetically transformed plant which has an increased oleic acid content, comprising a recombinant, double-stranded DNA molecule comprising

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

22. A method of producing a genetically transformed plant which has an elevated linolenic acid content, comprising

(a) inserting into the genome of a plant cell a recombinant, double-stranded DNA molecule comprising:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence;

(b) obtaining transformed plant cells; and

(c) regenerating from the transformed plant cells genetically transformed plants which have an elevated linolenic acid content.

23. The method of claim 22 in which the linoleic acid desaturase enzyme is from plants.

24. The method of claim 22 in which the linoleic acid desaturase enzyme is from fungi, algae or bacteria.

25. The method of claim 22 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:1.

26. The method of claim 22 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:9.

27. The method of claim 22 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:11.

28. The plant of claim 22 in which the promoter of (i) is an endogenous plant linoleic acid desaturase promoter.

29. A method of producing a genetically transformed plant which has a reduced linolenic acid content, comprising

(a) inserting into the genome of a plant cell a recombinant, double-stranded DNA molecule comprising:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence

(b) obtaining transformed plant cells; and

(c) regenerating from the transformed plant cells genetically transformed plants which have a reduced linolenic acid content.

30. The method of claim 29 in which the linoleic acid desaturase enzyme is from plants.

31. The method of claim 29 in which the linoleic acid desaturase enzyme is from fungi, algae or bacteria.

32. The method of claim 29 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:1.

33. The method of claim 29 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:9.

34. The method of claim 29 in which the structural coding sequence of (ii) is taken from SEQ. ID NO:11.

35. The plant of claim 29 in which the promoter of (i) is an endogenous plant linoleic acid desaturase promoter.

36. A method of producing a genetically transformed plant which has an increased oleic acid content, comprising

(a) inserting into the genome of a plant cell a recombinant, double-stranded DNA molecule comprising:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a

gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence

(b) obtaining transformed plant cells; and

(c) regenerating from the transformed plant cells genetically transformed plants which have an increased oleic acid content.

37. A recombinant, double-stranded DNA molecule comprising in sequence:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a structural coding sequence that causes the production of an RNA sequence that encodes a linoleic acid desaturase activity; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

38. A recombinant, double-stranded DNA molecule comprising in sequence:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

39. A plant cell comprising a recombinant, double-stranded DNA molecule comprising in sequence:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a linoleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence.

40. A method of producing a genetically transformed plant which has an increased oleic acid content, comprising

(a) inserting into the genome of a plant cell a recombinant, double-stranded DNA molecule comprising:

(i) a promoter that functions in plant cells to cause the production of an RNA sequence, said promoter operably linked to;

(ii) a DNA sequence that causes the production of an RNA sequence that is in antisense orientation to at least a portion of a gene that encodes a oleic acid desaturase activity in said plant; and

(iii) a 3' non-translated region that functions in plant cells to promote polyadenylation to the 3' end of said RNA sequence

(b) obtaining transformed plant cells; and

(c) regenerating from the transformed plant cells genetically transformed plants which have an increased oleic acid content.

INTERNATIONAL SEARCH REPORT

Inte. ...al Application No
PCT/US 94/01321

A. CLASSIFICATION OF SUBJECT MATTER
IPC 5 C12N15/82 C12N15/53 C12N15/11 C12N5/10 A01H5/00
C11B1/00

According to International Patent Classification (IPC) or to both national classification and IPC

B. FIELDS SEARCHED

Minimum documentation searched (classification system followed by classification symbols)
IPC 5 C12N A01H C11B

Documentation searched other than minimum documentation to the extent that such documents are included in the fields searched

Electronic data base consulted during the international search (name of data base and, where practical, search terms used)

C. DOCUMENTS CONSIDERED TO BE RELEVANT

Category *	Citation of document, with indication, where appropriate, of the relevant passages	Relevant to claim No.
X	SCIENCE vol. 258, 20 November 1992, LANCASTER, PA US pages 1353 - 1355 ARONDEL, V., ET AL. 'Map-based cloning of a gene controlling omega-3 fatty acid desaturation in Arabidopsis'	37
Y	see the whole document	1,2,4,8, 9,11,17, 18,22, 23,25, 29,30, 32,38

-/--

[X] Further documents are listed in the continuation of box C.

[X] Patent family members are listed in annex.

* Special categories of cited documents :

"A" document defining the general state of the art which is not considered to be of particular relevance

"E" earlier document but published on or after the international filing date

"L" document which may throw doubts on priority claim(s) or which is cited to establish the publication date of another citation or other special reason (as specified)

"O" document referring to an oral disclosure, use, exhibition or other means

"P" document published prior to the international filing date but later than the priority date claimed

"T" later document published after the international filing date or priority date and not in conflict with the application but cited to understand the principle or theory underlying the invention

"X" document of particular relevance; the claimed invention cannot be considered novel or cannot be considered to involve an inventive step when the document is taken alone

"Y" document of particular relevance; the claimed invention cannot be considered to involve an inventive step when the document is combined with one or more other such documents, such combination being obvious to a person skilled in the art.

"&" document member of the same patent family

(54) Title: AN OLEOSIN 5' REGULATORY REGION FOR THE MODIFICATION OF PLANT SEED LIPID COMPOSITION

(57) Abstract

The present invention is directed to 5' regulatory regions of an *Arabidopsis* oleosin gene. The 5' regulatory regions, when operably linked to either the coding sequence of a heterologous gene or a sequence complementary to a native plant gene, direct expression of the coding sequence or complementary sequence in a plant seed. The regulatory regions are useful in expression cassettes and expression vectors for the transformation of plants. Also provided are methods of modulating the levels of a heterologous gene such as a fatty acid synthesis or lipid metabolism gene by transforming a plant with the subject expression cassettes and expression vectors.

AN OLEOSIN 5' REGULATORY REGION FOR THE MODIFICATION OF PLANT SEED LIPID COMPOSITION

BACKGROUND OF THE INVENTION

Seed oil content has traditionally been modified by plant breeding. The use of recombinant DNA technology to alter seed oil composition can accelerate this process and in some cases alter seed oils in a way that cannot be accomplished by breeding alone. The oil composition of *Brassica* has been significantly altered by modifying the expression of a number of lipid metabolism genes. Such manipulations of seed oil composition have focused on altering the proportion of endogenous component fatty acids. For example, antisense repression of the Δ12-desaturase gene in transgenic rapeseed has resulted in an increase in oleic acid of up to 83%. Topfer et al. 1995 *Science 268*:681-686.

There have been some successful attempts at modifying the composition of seed oil in transgenic plants by introducing new genes that allow the production of a fatty acid that the host plants were not previously capable of synthesizing. Van de Loo, et al. (1995 *Proc. Natl. Acad. Sci USA 92*:6743-6747) have been able to introduce a Δ12-hydroxylase gene into transgenic tobacco, resulting in the introduction of a novel fatty acid, ricinoleic acid, into its seed oil. The reported accumulation was modest from plants carrying constructs in which transcription of the hydroxylase gene was under the control of the cauliflower mosaic virus (CaMV) 35S promoter.

Similarly, tobacco plants have been engineered to produce low levels of petroselinic acid by expression of an acyl-ACP desaturase from coriander (Cahoon et al. 1992 *Proc. Natl. Acad. Sci USA 89*:11184-11188).

The long chain fatty acids (C18 and larger), have significant economic value both as nutritionally and medically important foods and as industrial commodities (Ohlrogge,J.B. 1994 *Plant Physiol. 104*:821-826). Linoleic (18:2 Δ9,12) and α-linolenic acid (18:3 Δ9,12,15) are essential fatty acids found in many seed oils. The levels of these fatty-acids have been manipulated in oil seed crops through breeding and biotechnology (Ohlrogge, et al. *1991 Biochim. Biophys. Acta 1082*:1-26; Topfer et al. 1995 *Science 268*:681-686). Additionally, the production of novel fatty acids in seed oils can be of considerable use in both human health and industrial applications.

Consumption of plant oils rich in γ-linolenic acid (GLA) (18:3 Δ6,9,12) is thought to alleviate hypercholesterolemia and other related clinical disorders which correlate with susceptibility to coronary heart disease (Brenner R.R. 1976 *Adv. Exp. Med. Biol. 83*:85-101). The therapeutic benefits of dietary GLA may result from its role as a precursor to prostaglandin synthesis (Weete, J.D. 1980 in *Lipid Biochemistry of Fungi and Other Organisms*, eds. Plenum Press, New York, pp. 59-62). Linoleic acid(18:2) (LA) is transformed into gamma linolenic acid (18:3) (GLA) by the enzyme Δ6-desaturase.

Few seed oils contain GLA despite high contents of the precursor linoleic acid. This is due to the absence of Δ6-desaturase activity in most plants. For example, only borage (*Borago officinalis*), evening primrose (*Oenothera biennis*), and currants (*Ribes nigrum*) produce appreciable amounts of linolenic acid. Of these three species, only *Oenothera* and Borage are cultivated as a commercial source for GLA. It would be beneficial if agronomic seed oils could be engineered to produce GLA in significant quantities by introducing a heterologous Δ6-desaturase gene. It would also be beneficial if other expression products associated with fatty acid synthesis and lipid metabolism could be produced in plants at high enough levels so that commercial production of a particular expression product becomes feasible.

As disclosed in U.S. Patent No. 5,552,306, a cyanobacterial Δ^6-desaturase gene has been recently isolated. Expression of this cyanobacterial gene in transgenic tobacco resulted in significant but low level GLA accumulation. (Reddy et al. 1996 *Nature Biotech. 14*:639-642). Applicant's copending U.S. Application Serial No. 08,366,779, discloses a Δ6-desaturase gene isolated from the plant *Borago officinalis* and its expression in tobacco under the control of the CaMV 35S promoter. Such expression resulted in significant but low level GLA and octadecatetraenoic acid (ODTA or OTA) accumulation in seeds. Thus, a need exists for a promoter which

functions in plants and which consistently directs high level expression of lipid metabolism genes in transgenic plant seeds.

Oleosins are abundant seed proteins associated with the phospholipid monolayer membrane of oil bodies. The first oleosin gene, L3, was cloned from maize by selecting clones whose in vitro translated products were recognized by an anti-L3 antibody (Vance et al. 1987 *J. Biol. Chem. 262:11275-11279*). Subsequently, different isoforms of oleosin genes from such different species as *Brassica*, soybean, carrot, pine, and *Arabidopsis* have been cloned (Huang, A.H.C., 1992, *Ann. Reviews Plant Phys. and Plant Mol. Biol. 43*:177-200; Kirik et al., 1996 *Plant Mol. Biol. 31*:413-417; Van Rooijen et al., 1992 *Plant Mol. Biol. 18*:1177-1179; Zou et al., *Plant Mol. Biol. 31*:429-433. Oleosin protein sequences predicted from these genes are highly conserved, especially for the central hydrophobic domain. All of these oleosins have the characteristic feature of three distinctive domains. An amphipathic domain of 40-60 amino acids is present at the N-terminus; a totally hydrophobic domain of 68-74 amino acids is located at the center; and an amphipathic α-helical domain of 33-40 amino acids is situated at the C-terminus (Huang, A.H.C. 1992).

The present invention provides 5' regulatory sequences from an oleosin gene which direct high level expression of lipid metabolism genes in transgenic plants. In accordance with the present invention,

chimeric constructs comprising an oleosin 5' regulatory region operably linked to coding sequence for a lipid metabolism gene such as a Δ6-desaturase gene are provided. Transgenic plants comprising the subject chimeric constructs produce levels of GLA approaching the level found in those few plant species which naturally produce GLA such as evening primrose (*Oenothera biennis*).

SUMMARY OF THE INVENTION

The present invention is directed to 5' regulatory regions of an *Arabidopsis* oleosin gene. The 5' regulatory regions, when operably linked to either the coding sequence of a heterologous gene or sequence complementary to a native plant gene, direct expression of the heterologous gene or complementary sequence in a plant seed.

The present invention thus provides expression cassettes and expression vectors comprising an oleosin 5' regulatory region operably linked to a heterologous gene or a sequence complementary to a native plant gene.

Plant transformation vectors comprising the expression cassettes and expression vectors are also provided as are plant cells transformed by these vectors, and plants and their progeny containing the vectors.

In one embodiment of the invention, the heterologous gene or complementary gene sequence is a fatty acid synthesis gene or a lipid metabolism gene.

In another aspect of the present invention, a method is provided for producing a plant with increased levels of a product of a fatty acid synthesis or lipid metabolism gene.

In particular, there is provided a method for producing a plant with increased levels of a fatty acid synthesis or lipid metabolism gene by transforming a plant with the subject expression cassettes and expression vectors which comprise an oleosin 5' regulatory region and a coding sequence for a fatty acid synthesis or lipid metabolism gene.

In another aspect of the present invention, there is provided a method for cosuppressing a native fatty acid synthesis or lipid metabolism gene by transforming a plant with the subject expression cassettes and expression vectors which comprise an oleosin 5' regulatory region and a coding sequence for a fatty acid synthesis or lipid metabolism gene.

A further aspect of this invention provides a method of decreasing production of a native plant gene such as a fatty acid synthesis gene or a lipid metabolism gene by transforming a plant with an expression vector comprising a oleosin 5' regulatory region operably linked to a nucleic acid sequence complementary to a native plant gene.

Also provided are methods of modulating the levels of a heterologous gene such as a fatty acid synthesis or lipid metabolism gene by transforming a plant with the subject expression cassettes and expression vectors.

BRIEF DESCRIPTION OF THE DRAWINGS

Fig. 1 depicts the nucleotide and corresponding amino acid sequence of the borage Δ6-desaturase gene (SEQ ID NO:1). The cytochrome b5 heme-binding motif is boxed and the putative metal binding, histidine rich motifs (HRMs) are underlined. The motifs recognized by the primers (PCR analysis) are underlined with dotted lines, i.e. tgg aaa tgg aac cat aa; and gag cat cat ttg ttt cc.

Fig. 2 is a dendrogram showing similarity of the borage Δ6-desaturase to other membrane-bound desaturases. The amino acid sequence of the borage Δ6-desaturase was compared to other known desaturases using Gene Works (IntelliGenetics). Numerical values correlate to relative phylogenetic distances between subgroups compared.

Fig. 3A provides a gas liquid chromatography profile of the fatty acid methyl esters (FAMES) derived from leaf tissue of a wild type tobacco 'Xanthi'.

Fig. 3B provides a gas liquid chromatography profile of the FAMES derived from leaf tissue of a tobacco plant transformed with the borage Δ6-desaturase cDNA under transcriptional control of the CaMV 35S promoter (pAN2). Peaks corresponding to methyl linoleate (18:2), methyl γ-linolenate (18:3γ), methyl α-linolenate (18:3α), and methyl octadecatetraenoate (18:4) are indicated.

Fig. 4 is the nucleotide sequence and corresponding amino acid sequence of the oleosin AtS21 cDNA (SEQ ID NO:3).

Fig. 5 is an acidic-base map of the predicted AtS21 protein generated by DNA Strider 1.2.

Fig. 6 is a Kyte-Doolittle plot of the predicted AtS21 protein generated by DNA Strider 1.2.

Fig. 7 is a sequence alignment of oleosins isolated from *Arabidopsis*. Oleosin sequences published or deposited in EMBL, BCM, NCBI databases were aligned to each other using GeneWorks® 2.3. Identical residues are boxed with rectangles. The seven sequences fall into three groups. The first group includes AtS21 (SEQ ID NO:5), X91918 (SEQ ID NO:6) and Z29859 (SEQ ID NO:7). The second group includes X62352 (SEQ ID NO:8) and Ato13 (SEQ ID NO:9). The third group includes X91956 (SEQ ID NO:10) and L40954 (SEQ ID NO:11). Differences in amino acid residues within the same group are indicated by shadows. Ato2/Z54164 is identical to AtS21. Ato13 sequence (Accession No. Z541654 in EMBL database) is actually not disclosed in the EMBL database. The Z54165 Accession number designates the same sequence as Z54164 which is Ato12.

Fig. 8A is a Northern analysis of the AtS21 gene. An RNA gel blot containing ten micrograms of total RNA extracted from *Arabidopsis* flowers (F), leaves (L), roots (R), developing seeds (Se), and developing silique coats (Si) was hybridized with a probe made from the full-length AtS21 cDNA.

Fig. 8B is a Southern analysis of the AtS21 gene. A DNA gel blot containing ten micrograms of genomic DNA digested with BamHI (B), EcoRI (E), HindIII (H), SacI (S), and XbaI (X) was hybridized with a probe made from the full length AtS21 cDNA.

Fig. 9 is the nucleotide sequence of the SacI fragment of AtS21 genomic DNA (SEQ ID NO:12). The promoter and intron sequences are in uppercase. The fragments corresponding to AtS21 cDNA sequence are in lower case. The first ATG codon and a putative TATA box are shadowed. The sequence complementary to 21P primer for PCR amplification is boxed. A putative abscisic acid response element (ABRE) and two 14 bp repeats are underlined.

Fig. 10 is a map of AtS21 promoter/GUS construct (pAN5).

Fig. 11A depicts AtS21/GUS gene expression in *Arabidopsis* bolt and leaves.

Fig. 11B depicts AtS21 GUS gene expression in *Arabidopsis* siliques.

Fig. 11C depicts AtS21 GUS gene expression in *Arabidopsis* developing seeds.

Figs. 11D through 11J depict AtS21 GUS gene expression in *Arabidopsis* developing embryos.

Fig. 11K depicts AtS21/GUS gene expression in *Arabidopsis* root and root hairs of a young seedling.

Fig. 11L depicts AtS21/GUS gene expression in *Arabidopsis* cotyledons and the shoot apex of a five day seedling.

Figs. 11M and 11N depict AtS21/GUS gene expression in *Arabidopsis* cotyledons and the shoot apex of 5-15 day seedlings.

Fig. 12A depicts AtS21/GUS gene expression in tobacco embryos and endosperm.

Fig. 12B depicts AtS21/GUS gene expression in germinating tobacco seeds.

Fig. 12C depicts AtS21/GUS gene expression in a 5 day old tobacco seedling.

Fig. 12D depicts AtS21/GUS gene expression in 5-15 day old tobacco seedlings.

Fig. 13A is a Northern analysis showing AtS21 mRNA levels in developing wild-type *Arabidopsis* seedlings. Lane 1 was loaded with RNA from developing seeds, lane 2 was loaded with RNA from seeds imbibed for 24-48 hours, lane 3: 3 day seedlings; lane 4: 4 day seedlings; lane 5: 5 day seedlings; lane 6: 6 day seedlings; lane 7; 9 day seedlings; lane 8: 12 day seedlings. Probe was labeled AtS21 cDNA. Exposure was for one hour at -80°C.

Fig. 13B is the same blot as Fig. 13A only exposure was for 24 hours at -80°C.

Fig. 13C is the same blot depicted in Figs. 13A and 13B after stripping and hybridization with an *Arabidopsis* tubulin gene probe. The small band in each of lanes 1 and 2 is the remnant of the previous AtS21 probe. Exposure was for 48 hours at -80°C.

Fig. 14 is a graph comparing GUS activities expressed by the AtS21 and 35S promoters. GUS activities expressed by the AtS21 promoter in

developing *Arabidopsis* seeds and leaf are plotted side by side with those expressed by the 35S promoter. The GUS activities expressed by the AtS21 promoter in tobacco dry seed and leaf are plotted on the right side of the figure. GUS activity in tobacco leaf is so low that no column appears. "G-H" denotes globular to heart stage; "H-T" denotes heart to torpedo stage; "T-C" denotes torpedo to cotyledon stage; "Early C" denotes early cotyledon; "Late C" denotes late cotyledon. The standard deviations are listed in Table 2.

Fig. 15A is an RNA gel blot analysis carried out on 5 μg samples of RNA isolated from borage leaf, root, and 12 dpp embryo tissue, using labeled borage Δ6-desaturase cDNA as a hybridization probe.

Fig. 15B depicts a graph corresponding to the Northern analysis results for the experiment shown in Fig. 15A.

Fig. 16A is a graph showing relative legumin RNA accumulation in developing borage embryos based on results of Northern blot.

Fig. 16B is a graph showing relative oleosin RNA accumulation in developing borage embryos based on results of Northern blot.

Fig. 16C is a graph showing relative Δ6-desaturase RNA accumulation in developing borage embryos based on results of Northern blot.

Fig. 17 is a PCR analysis showing the presence of the borage delta 6-desaturase gene in transformed plants of oilseed rape. Lanes 1, 3 and 4

were loaded with PCR reactions performed with DNA from plants transformed with the borage delta 6-desaturase gene linked to the oleosin 5' regulatory region; lane 2: DNA from plant transformed with the borage delta 6-desaturase gene linked to the albumin 5' regulatory region; lanes 5 and 6: DNA from non-transformed plants; lane 7: molecular weight marker (1 kb ladder, Gibco BRL); lane 8: PCR without added template DNA; lane 9: control with DNA from *Agrobacterium tumefaciens* EHA 105 containing the plasmid pAN3 (i.e. the borage delta6-desaturase gene linked to the oleosin 5' regulatory region).

DETAILED DESCRIPTION OF THE INVENTION

The present invention provides isolated nucleic acids encoding 5' regulatory regions from an *Arabidopsis* oleosin gene. In accordance with the present invention, the subject 5' regulatory regions, when operably linked to either a coding sequence of a heterologous gene or a sequence complementary to a native plant gene, direct expression of the coding sequence or complementary sequence in a plant seed. The oleosin 5' regulatory regions of the present invention are useful in the construction of an expression cassette which comprises in the 5' to 3' direction, a subject oleosin 5' regulatory region, a heterologous gene or sequence complementary to a native plant gene under control of the regulatory region and a 3' termination sequence. Such an expression cassette can be incorporated into a variety

of autonomously replicating vectors in order to construct an expression vector.

It has been surprisingly found that plants transformed with the expression vectors of the present invention produce levels of GLA approaching the level found in those few plant species which naturally produce GLA such as evening primrose *(Oenothera biennis)*.

As used herein, the term "cassette" refers to a nucleotide sequence capable of expressing a particular gene if said gene is inserted so as to be operably linked to one or more regulatory regions present in the nucleotide sequence. Thus, for example, the expression cassette may comprise a heterologous coding sequence which is desired to be expressed in a plant seed. The expression cassettes and expression vectors of the present invention are therefore useful for directing seed-specific expression of any number of heterologous genes. The term "seed-specific expression" as used herein, refers to expression in various portions of a plant seed such as the endosperm and embryo.

An isolated nucleic acid encoding a 5' regulatory region from an oleosin gene can be provided as follows. Oleosin recombinant genomic clones are isolated by screening a plant genomic DNA library with a cDNA (or a portion thereof) representing oleosin mRNA. A number of different oleosin cDNAs have been isolated. The methods used to isolate such cDNAs as well as the nucleotide and corresponding amino acid

sequences have been published in Kirik et al. 1986 *Plant Mol. Biol. 31*:413-417; Zou et al. *Plant Mol. Biol. 31*:429-433; Van Rooigen et al. 1992 *Plant Mol. Biol. 18*:1177-1179.

Virtual subtraction screening of a tissue specific library using a random primed polymerase chain (RP-PCR) cDNA probe is another method of obtaining an oleosin cDNA useful for screening a plant genomic DNA library. Virtual subtraction screening refers to a method where a cDNA library is constructed from a target tissue and displayed at a low density so that individual cDNA clones can be easily separated. These cDNA clones are subtractively screened with driver quantities (i.e., concentrations of DNA to kinetically drive the hybridization reaction) of cDNA probes made from tissue or tissues other than the target tissue (i.e. driver tissue). The hybridized plaques represent genes that are expressed in both the target and the driver tissues; the unhybridized plaques represent genes that may be target tissue-specific or low abundant genes that can not be detected by the driver cDNA probe. The unhybridized cDNAs are selected as putative target tissue-specific genes and further analyzed by one-pass sequencing and Northern hybridization.

Random primed PCR (RP-PCR) involves synthesis of large quantities of cDNA probes from a trace amount of cDNA template. The method combines the amplification power of PCR with the representation

of random priming to simultaneously amplify and label double-stranded cDNA in a single tube reaction.

Methods considered useful in obtaining oleosin genomic recombinant DNA are provided in Sambrook et al. 1989, in *Molecular Cloning: A Laboratory Manual*, Cold Spring Harbor, NY, for example, or any of the myriad of laboratory manuals on recombinant DNA technology that are widely available. To determine nucleotide sequences, a multitude of techniques are available and known to the ordinarily skilled artisan. For example, restriction fragments containing an oleosin regulatory region can be subcloned into the polylinker site of a sequencing vector such as pBluescript (Stratagene). These pBluescript subclones can then be sequenced by the double-stranded dideoxy method (Chen and Seeburg, 1985, *DNA* 4:165).

In a preferred embodiment, the oleosin regulatory region comprises nucleotides 1-1267 of Fig. 9 (SEQ ID NO:12). Modifications to the oleosin regulatory region as set forth in SEQ ID NO:12 which maintain the characteristic property of directing seed-specific expression, are within the scope of the present invention. Such modifications include insertions, deletions and substitutions of one or more nucleotides.

The 5' regulatory region of the present invention can be derived from restriction endonuclease or exonuclease digestion of an oleosin genomic clone. Thus, for example, the known nucleotide or amino acid

sequence of the coding region of an isolated oleosin gene (e.g. Fig. 7) is aligned to the nucleic acid or deduced amino acid sequence of an isolated oleosin genomic clone and 5' flanking sequence (i.e., sequence upstream from the translational start codon of the coding region) of the isolated oleosin genomic clone located.

The oleosin 5' regulatory region as set forth in SEQ ID NO:12 (nucleotides 1-1267 of Fig. 9) may be generated from a genomic clone having either or both excess 5' flanking sequence or coding sequence by exonuclease III-mediated deletion. This is accomplished by digesting appropriately prepared DNA with exonuclease III (exoIII) and removing aliquots at increasing intervals of time during the digestion. The resulting successively smaller fragments of DNA may be sequenced to determine the exact endpoint of the deletions. There are several commercially available systems which use exonuclease III (exoIII) to create such a deletion series, e.g. Promega Biotech, "Erase-A-Base" system. Alternatively, PCR primers can be defined to allow direct amplification of the subject 5' regulatory regions.

Using the same methodologies, the ordinarily skilled artisan can generate one or more deletion fragments of nucleotides 1-1267 as set forth in SEQ ID NO:12. Any and all deletion fragments which comprise a contiguous portion of nucleotides set forth in SEQ ID NO:12 and which retain the capacity to

direct seed-specific expression are contemplated by the present invention.

The identification of oleosin 5' regulatory sequences which direct seed-specific expression comprising nucleotides 1-1267 of SEQ ID NO:12 and modifications or deletion fragments thereof, can be accomplished by transcriptional fusions of specific sequences with the coding sequences of a heterologous gene, transfer of the chimeric gene into an appropriate host, and detection of the expression of the heterologous gene. The assay used to detect expression depends upon the nature of the heterologous sequence. For example, reporter genes, exemplified by chloramphenicol acetyl transferase and β-glucuronidase (GUS), are commonly used to assess transcriptional and translational competence of chimeric constructions. Standard assays are available to sensitively detect the reporter enzyme in a transgenic organism. The β-glucuronidase (GUS) gene is useful as a reporter of promoter activity in transgenic plants because of the high stability of the enzyme in plant cells, the lack of intrinsic β-glucuronidase activity in higher plants and availability of a quantitative fluorimetric assay and a histochemical localization technique. Jefferson et al. (1987 *EMBO J 6*:3901) have established standard procedures for biochemical and histochemical detection of GUS activity in plant tissues. Biochemical assays are performed by mixing plant tissue lysates with 4-methylumbelliferyl-β-D-glucuronide, a fluorimetric substrate for GUS, incubating one hour at 37°C, and

then measuring the fluorescence of the resulting 4-methyl-umbelliferone. Histochemical localization for GUS activity is determined by incubating plant tissue samples in 5-bromo-4-chloro-3-indolyl-glucuronide (X-Gluc) for about 18 hours at 37°C and observing the staining pattern of X-Gluc. The construction of such chimeric genes allows definition of specific regulatory sequences and demonstrates that these sequences can direct expression of heterologous genes in a seed-specific manner.

Another aspect of the invention is directed to expression cassettes and expression vectors (also termed herein "chimeric genes") comprising a 5' regulatory region from an oleosin gene which directs seed specific expression operably linked to the coding sequence of a heterologous gene such that the regulatory element is capable of controlling expression of the product encoded by the heterologous gene. The heterologous gene can be any gene other than oleosin. If necessary, additional regulatory elements or parts of these elements sufficient to cause expression resulting in production of an effective amount of the polypeptide encoded by the heterologous gene are included in the chimeric constructs.

Accordingly, the present invention provides chimeric genes comprising sequences of the oleosin 5' regulatory region that confer seed-specific expression which are operably linked to a sequence encoding a heterologous gene such as a lipid metabolism enzyme.

Examples of lipid metabolism genes useful for practicing the present invention include lipid desaturases such as Δ6-desaturases, Δ12-desaturases, Δ15-desaturases and other related desaturases such as stearoyl-ACP desaturases, acyl carrier proteins (ACPs), thioesterases, acetyl transacylases, acetyl-coA carboxylases, ketoacyl-synthases, malonyl transacylases, and elongases. Such lipid metabolism genes have been isolated and characterized from a number of different bacteria and plant species. Their nucleotide coding sequences as well as methods of isolating such coding sequences are disclosed in the published literature and are widely available to those of skill in the art.

In particular, the Δ6-desaturase genes disclosed in U.S. Patent No. 5,552,306 and applicants' copending U.S. Application Serial No. 08/366,779 filed December 30, 1994 and incorporated herein by reference, are contemplated as lipid metabolism genes particularly useful in the practice of the present invention.

The chimeric genes of the present invention are constructed by ligating a 5' regulatory region of a oleosin genomic DNA to the coding sequence of a heterologous gene. The juxtaposition of these sequences can be accomplished in a variety of ways. In a preferred embodiment the order of the sequences, from 5' to 3', is an oleosin 5' regulatory region (including a promoter), a coding sequence, and a

termination sequence which includes a polyadenylation site.

Standard techniques for construction of such chimeric genes are well known to those of ordinary skill in the art and can be found in references such as Sambrook et al.(1989). A variety of strategies are available for ligating fragments of DNA, the choice of which depends on the nature of the termini of the DNA fragments. One of ordinary skill in the art recognizes that in order for the heterologous gene to be expressed, the construction requires promoter elements and signals for efficient polyadenylation of the transcript. Accordingly, the oleosin 5' regulatory region that contains the consensus promoter sequence known as the TATA box can be ligated directly to a promoterless heterologous coding sequence.

The restriction or deletion fragments that contain the oleosin TATA box are ligated in a forward orientation to a promoterless heterologous gene such as the coding sequence of β-glucuronidase (GUS). The skilled artisan will recognize that the subject oleosin 5' regulatory regions can be provided by other means, for example chemical or enzymatic synthesis. The 3' end of a heterologous coding sequence is optionally ligated to a termination sequence comprising a polyadenylation site, exemplified by, but not limited to, the nopaline synthase polyadenylation site, or the octopine T-DNA gene 7 polyadenylation site. Alternatively, the polyadenylation site can be provided by the heterologous gene.

The present invention also provides methods of increasing levels of heterologous genes in plant seeds. In accordance with such methods, the subject expression cassettes and expression vectors are introduced into a plant in order to effect expression of a heterologous gene. For example, a method of producing a plant with increased levels of a product of a fatty acid synthesis or lipid metabolism gene is provided by transforming a plant cell with an expression vector comprising an oleosin 5' regulatory region operably linked to a fatty acid synthesis or lipid metabolism gene and regenerating a plant with increased levels of the product of said fatty acid synthesis or lipid metabolism gene.

Another aspect of the present invention provides methods of reducing levels of a product of a gene which is native to a plant which comprises transforming a plant cell with an expression vector comprising a subject oleosin regulatory region operably linked to a nucleic acid sequence which is complementary to the native plant gene. In this manner, levels of endogenous product of the native plant gene are reduced through the mechanism known as antisense regulation. Thus, for example, levels of a product of a fatty acid synthesis gene or lipid metabolism gene are reduced by transforming a plant with an expression vector comprising a subject oleosin 5' regulatory region operably linked to a nucleic acid sequence which is complementary to a nucleic acid

sequence coding for a native fatty acid synthesis or lipid metabolism gene.

The present invention also provides a method of cosuppressing a gene which is native to a plant which comprises transforming a plant cell with an expression vector comprising a subject oleosin 5' regulatory region operably linked to a nucleic acid sequence coding for the native plant gene. In this manner, levels of endogenous product of the native plant gene are reduced through the mechanism known as cosuppression. Thus, for example, levels of a product of a fatty acid synthesis gene or lipid metabolism gene are reduced by transforming a plant with an expression vector comprising a subject oleosin 5' regulatory region operably linked to a nucleic acid sequence coding for a native fatty acid synthesis or lipid metabolism gene native to the plant. Although the exact mechanism of cosuppression is not completely understood, one skilled in the art is familiar with published works reporting the experimental conditions and results associated with cosuppression (Napoli et al. 1990 *The Plant Cell 2*:270-289; Van der Krol 1990 *The Plant Cell 2*:291-299.

To provide regulated expression of the heterologous or native genes, plants are transformed with the chimeric gene constructions of the invention. Methods of gene transfer are well known in the art. The chimeric genes can be introduced into plants by leaf disk transformation-regeneration procedure as described by Horsch et al. 1985 *Science 227*:1229.

Other methods of transformation such as protoplast culture (Horsch et al. 1984 *Science 223*:496, DeBlock et al. 1984 *EMBO J. 2*:2143, Barton et al. 1983, *Cell 32*:1033) can also be used and are within the scope of this invention. In a preferred embodiment, plants are transformed with *Agrobacterium*-derived vectors such as those described in Klett et al. (1987) *Annu. Rev. Plant Physiol. 38*:467. Other well-known methods are available to insert the chimeric genes of the present invention into plant cells. Such alternative methods include biolistic approaches (Klein et al. 1987 *Nature 327*:70), electroporation, chemically-induced DNA uptake, and use of viruses or pollen as vectors.

When necessary for the transformation method, the chimeric genes of the present invention can be inserted into a plant transformation vector, e.g. the binary vector described by Bevan, M. 1984 *Nucleic Acids Res. 12*:8711-8721. Plant transformation vectors can be derived by modifying the natural gene transfer system of *Agrobacterium tumefaciens*. The natural system comprises large Ti (tumor-inducing)-plasmids containing a large segment, known as T-DNA, which is transferred to transformed plants. Another segment of the Ti plasmid, the *vir* region, is responsible for T-DNA transfer. The T-DNA region is bordered by terminal repeats. In the modified binary vectors, the tumor inducing genes have been deleted and the functions of the *vir* region are utilized to transfer foreign DNA bordered by the T-DNA border sequences. The T-region also contains a selectable

marker for antibiotic resistance, and a multiple cloning site for inserting sequences for transfer. Such engineered strains are known as "disarmed" *A. tumefaciens* strains, and allow the efficient transfer of sequences bordered by the T-region into the nuclear genome of plants.

Surface-sterilized leaf disks and other susceptible tissues are inoculated with the "disarmed" foreign DNA-containing *A. tumefaciens*, cultured for a number of days, and then transferred to antibiotic-containing medium. Transformed shoots are then selected after rooting in medium containing the appropriate antibiotic, and transferred to soil. Transgenic plants are pollinated and seeds from these plants are collected and grown on antibiotic medium.

Expression of a heterologous or reporter gene in developing seeds, young seedlings and mature plants can be monitored by immunological, histochemical or activity assays. As discussed herein, the choice of an assay for expression of the chimeric gene depends upon the nature of the heterologous coding region. For example, Northern analysis can be used to assess transcription if appropriate nucleotide probes are available. If antibodies to the polypeptide encoded by the heterologous gene are available, Western analysis and immunohistochemical localization can be used to assess the production and localization of the polypeptide. Depending upon the heterologous gene, appropriate biochemical assays can be used. For example,

acetyltransferases are detected by measuring acetylation of a standard substrate. The expression of a lipid desaturase gene can be assayed by analysis of fatty acid methyl esters (FAMES).

Another aspect of the present invention provides transgenic plants or progeny of these plants containing the chimeric genes of the invention. Both monocotyledonous and dicotyledonous plants are contemplated. Plant cells are transformed with the chimeric genes by any of the plant transformation methods described above. The transformed plant cell, usually in the form of a callus culture, leaf disk, explant or whole plant (via the vacuum infiltration method of Bechtold et al. 1993 *C.R. Acad. Sci. Paris*, *316*:1194-1199) is regenerated into a complete transgenic plant by methods well-known to one of ordinary skill in the art (e.g. Horsch et al. 1985 *Science 227*:1129). In a preferred embodiment, the transgenic plant is sunflower, cotton, oil seed rape, maize, tobacco, *Arabidopsis*, peanut or soybean. Since progeny of transformed plants inherit the chimeric genes, seeds or cuttings from transformed plants are used to maintain the transgenic line.

The following examples further illustrate the invention.

EXAMPLE 1

Isolation of Membrane-Bound Polysomal RNA and Construction of Borage cDNA Library

Membrane-bound polysomes were isolated from borage seeds 12 days post pollination (12 DPP)using the protocol established for peas by Larkins and Davies (1975 *Plant Phys. 55:* 749-756). RNA was extracted from the polysomes as described by Mechler (1987 *Methods in Enzymology 152:* 241-248, Academic Press). Poly-A^+ RNA was isolated from the membrane bound polysomal RNA using Oligotex-dT™ beads (Qiagen).

Corresponding cDNA was made using Stratagene's ZAP cDNA synthesis kit. The cDNA library was constructed in the lambda ZAP II vector (Stratagene) using the lambda ZAP II kit. The primary library was packaged with Gigapack II Gold packaging extract (Stratagene).

EXAMPLE 2

Isolation of a Δ-6 Desaturase cDNA from Borage

Hybridization protocol

The amplified borage cDNA library was plated at low density (500 pfu on 150 mm petri dishes). Highly prevalent seed storage protein cDNAs were reduced (subtracted from the total cDNAs) by screening with the corresponding cDNAs.

Hybridization probes for screening the borage cDNA library were generated by using random primed DNA synthesis as described by Ausubel et al (1994 Current Protocols in Molecular Biology, Wiley Interscience, N.Y.) and corresponded to previously identified abundantly expressed seed storage protein cDNAs. Unincorporated nucleotides were removed by use of a G-50 spin column (Boehringer Manheim). Probe was denatured for hybridization by boiling in a water bath for 5 minutes, then quickly cooled on ice. Nitrocellulose filters carrying fixed recombinant bacteriophage were prehybridized at 60°C for 2-4 hours in hybridization solution [4X SET (600 mM NaCl, 80 mM Tris-HCl, 4 mM Na_2EDTA; pH 7.8), 5X Denhardt's reagent (0.1% bovine serum albumin, 0.1% Ficoll, and 0.1% polyvinylpyrolidone), 100 μg/ml denatured salmon sperm DNA, 50 μg/ml polyadenine and 10 ug/ml polycytidine]. This was replaced with fresh hybridization solution to which denatured radioactive probe (2 ng/ml hybridization solution) was added. The filters were incubated at 60°C with agitation overnight. Filters

were washed sequentially in 4X, 2X, and 1X SET (150 mM NaCl, 20 mM Tris-HCl, 1 mM Na_2EDTA; pH7.8) for 15 minutes each at 60°C. Filters were air dried and then exposed to X-ray film for 24 hours with intensifying screens at -80°C.

Non-hybridizing plaques were excised using Stratagene's excision protocol and reagents. Resulting bacterial colonies were used to inoculate liquid cultures and were either sequenced manually or by an ABI automated sequencer.

Random Sequencing of cDNAs from a Borage Seed 12 (DPP) Membrane-Bound Polysomal Library

Each cDNA corresponding to a non-hybridizing plaque was sequenced once and a sequence tag generated from 200-300 base pairs. All sequencing was performed by cycle sequencing (Epicentre). Over 300 expressed sequence tags (ESTs) were generated. Each sequence tag was compared to the GenBank database using the BLAST algorithm (Altschul et al. 1990 *J. Mol. Biol. 215*:403-410). A number of lipid metabolism genes, including the Δ6-desaturase were identified.

Database searches with the cDNA clone designated mbp-65 using BLASTX with the GenBank database resulted in a significant match to the previously isolated *Synechocystis* Δ6-desaturase. It was determined however, that mbp-65 was not a full length cDNA. A full length cDNA was isolated using mbp-65 to screen the borage membrane-bound polysomal library. The resultant clone was designated pAN1 and the cDNA insert of pAN1 was sequenced by the cycle

sequencing method. The amino acid sequence deduced from the open reading frame (Fig. 1, SEQ ID NO:1) was compared to other known desaturases using Geneworks (IntelligGenetics) protein alignment program. This alignment indicated that the cDNA insert of pAN1 was the borage Δ6-desaturase gene.

The resulting dendrogram (Figure 2) shows that Δ^{15}-desaturases and Δ^{12}-desaturases comprise two groups. The newly isolated borage sequence and the previously isolated *Synechocystis* Δ^{6}-desaturase (U.S. Patent No. 5,552,306) formed a third distinct group. A comparison of amino acid motifs common to desaturases and thought to be involved catalytically in metal binding illustrates the overall similarity of the protein encoded by the borage gene to desaturases in general and the *Synechocystis* Δ^{6}-desaturase in particular (Table 1). At the same time, comparison of the motifs in Table 1 indicates definite differences between this protein and other plant desaturases. Furthermore, the borage sequence is also distinguished from known plant membrane associated fatty acid desaturases by the presence of a heme binding motif conserved in cytochrome b_5 proteins (Schmidt et al. 1994 *Plant Mol. Biol. 26*:631-642)(Figure 1). Thus, while these results clearly suggested that the isolated cDNA was a borage Δ^{6}-desaturase gene, further confirmation was necessary. To confirm the identity of the borage Δ6-desaturase cDNA, the cDNA insert from pAN1 was cloned into an expression cassette for stable expression. The vector pBI121 (Jefferson et al. 1987

EMBO J. 6:3901-3907) was prepared for ligation by digestion with BamHI and EcoICR I (an isoschizomer of SacI which leaves blunt ends; available from Promega) which excises the GUS coding region leaving the 35S promoter and NOS terminator intact. The borage Δ^6-desaturase cDNA was excised from the recombinant plasmid (pAN1) by digestion with BamHI and XhoI. The XhoI end was made blunt by performing a fill-in reaction catalyzed by the Klenow fragment of DNA polymerase I. This fragment was then cloned into the BamHI/EcoICR I sites of pBI121.1, resulting in the plasmid pAN2.

TABLE 1

COMPARISON OF COMMON AMINO ACID MOTIFS IN MEMBRANE-BOUND DESATURASES

Desaturase	Lipid Box	Metal Box 1	Metal Box 2

*P1-81 is a full length cDNA which was identified by EST analysis and shows high similarity to the Arbidopsis Δ12 desaturase (fad2)

EXAMPLE 3

Production of Transgenic Plants and Preparation and Analysis of Fatty Acid Methyl Esters (FAMEs)

The expression plasmid, pAN2 was used to transform tobacco (*Nicotiana tabacum* cv. *xanthi*) via *Agrobacterium tumefaciens* according to standard procedures (Horsch, et al. 1985 *Science* 227:1229-1231; Bogue et al. 1990 *Mol. Gen. Genet. 221:*49-57) except that the initial transformants were selected on 100 μg/ml kanamycin.

Tissue from transgenic plants was frozen in liquid nitrogen and lyophilized overnight. FAMEs were prepared as described by Dahmer, et al. (1989) *J. Amer. Oil. Chem. Soc. 66:* 543-548. In some cases, the solvent was evaporated again, and the FAMEs were resuspended in ethyl acetate and extracted once with deionized water to remove any water soluble contaminants. FAMEs were analyzed using a Tracor-560 gas liquid chromatograph as previously described (Reddy et al. 1996 *Nature Biotech. 14*:639-642).

As shown in Figure. 3, transgenic tobacco leaves containing the borage cDNA produced both GLA and octadecatetraenoic acid (OTA) (18:4 Δ6,9,12,15). These results thus demonstrate that the isolated cDNA encodes a borage Δ6-desaturase.

EXAMPLE 4

Expression of Δ6-desaturase in Borage

The native expression of Δ6-desaturase was examined by Northern Analysis of RNA derived from borage tissues. RNA was isolated from developing borage embryos following the method of Chang et al. 1993 *Plant Mol. Biol. Rep. 11*:113-116. RNA was electrophoretically separated on formaldehyde-agarose gels, blotted to nylon membranes by capillary transfer, and immobilized by baking at 80°C for 30 minutes following standard protocols (Brown T., 1996 in *Current Protocols in Molecular Biology,* eds. Auselbel, et al. [Greene Publishing and Wiley-Interscience, New York] pp. 4.9.1-4.9.14.). The filters were preincubated at 42°C in a solution containing 50% deionized formamide, 5X Denhardt's reagent, 5X SSPE (900 mM NaCl; 50mM Sodium phosphate, pH7.7; and 5 mM EDTA), 0.1% SDS, and 200 μg/ml denatured salmon sperm DNA. After two hours, the filters were added to a fresh solution of the same composition with the addition of denatured radioactive hybridization probe. In this instance, the probes used were borage legumin cDNA (Fig. 16A), borage oleosin cDNA (Fig. 16B), and borage Δ6-desaturase cDNA (pAN1, Example 2)(Fig. 16C). The borage legumin and oleosin cDNAs were isolated by EST cloning and identified by comparison to the GenBank database using the BLAST algorithm as described in Example 2. Loading variation was corrected by normalizing to

levels of borage EF1α mRNA. EF1α mRNA was identified by correlating to the corresponding cDNA obtained by the EST analysis described in Example 2. The filters were hybridized at 42°C for 12-20 hours, then washed as described above (except that the temperature was 65°C), air dried, and exposed to X-ray film.

As depicted in Figs. 15A and 15B, Δ6-desaturase is expressed primarily in borage seed. Borage seeds reach maturation between 18-20 days post pollination (dpp). Δ6-desaturase mRNA expression occurs throughout the time points collected (8-20 dpp), but appears maximal from 10-16 days post pollination. This expression profile is similar to that seen for borage oleosin and 12S seed storage protein mRNAs (Figs. 16A, 16B, and 16C).

EXAMPLE 5

Isolation and Characterization of a Novel Oleosin cDNA

The oleosin cDNA (AtS21) was isolated by virtual subtraction screening of an *Arabidopsis* developing seed cDNA library using a random primed polymerase chain reaction (RP-PCR) cDNA probe derived from root tissue.

RNA PREPARATION

Arabidopsis thaliana Landsberg *erecta* plants were grown under continuous illumination in a vermiculite/soil mixture at ambient temperature (22°C). Siliques 2-5 days after flowering were dissected to separately collect developing seeds and silique coats. Inflorescences containing initial flower buds and fully opened flowers, leaves, and whole siliques one or three days after flowering were also collected. Roots were obtained from seedlings that had been grown in Gamborg B_5 liquid medium (GIBCO BRL) for two weeks. The seeds for root culture were previously sterilized with 50% bleach for five minutes and rinsed with water extensively. All tissues were frozen in liquid nitrogen and stored at -80°C until use. Total RNAs were isolated following a hot phenol/SDS extraction and LiCl precipitation protocol (Harris et al. 1978 *Biochem.* *17*:3251-3256; Galau et al. 1981 *J. Biol. Chem.* *256*:2551-2560). Poly A+ RNA was isolated using oligo dT column chromatography according to manufacturers' protocols (PHARMACIA or

STRATAGENE) or using oligotex-dT latex particles (QIAGEN).

Construction of tissue-specific cDNA libraries

Flower, one day silique, three day silique, leaf, root, and developing seed cDNA libraries were each constructed from 5 µg poly A+ RN using the ZAP cDNA synthesis kit (Stratagene). cDNAs were directionally cloned into the EcoRI and XhoI sites of pBluescript SK(-) in the λ-ZAPII vector (Short et al. 1988 *Nucleic Acids Res.* 16:7583-7600). Nonrecombinant phage plaques were identified by blue color development on NZY plates containing X-gal (5 bromo-4-chloro-3-indoyl-β-D-galactopyranoside) and IPTG (isopropyl-1-thio-β-D-galactopyranoside). The nonrecombinant backgrounds for the flower, one day silique, three day silique, leaf, root, and developing seed cDNA libraries were 2.8%, 2%m 3.3%, 6.5%, 2.5%, and 1.9% respectively.

Random priming DNA labeling

The cDNA inserts of isolated clones (unhybridized cDNAs) were excised by EcoRI/XhoI double digestion and gel-purified for random priming labeling. Klenow reaction mixture contained 50 ng DNA templates, 10 mM Tris-HCl, pH 7.5, 5 mM $MgCl_2$, 7.5 mM DTT, 50 uM each of dCTP, dGTP, and dTTP, 10 uM hexamer random primbers (Boehringer Mannheim), 50 µCi α-32 P-dATP, 3000 Ci/mmole, 10 mCi/ml (DuPont), and 5 units of DNA polymerase I Klenow fragment (New England

Biolabs). The reactions were carried out at 37°C for one hour. Aliquots of diluted reaction mixtures were used for TCA precipitation and alkaline denaturing gel analysis. Hybridization probes were labeled only with Klenow DNA polymerase and the unincorporated dNTPs were removed using Sephadex R G-50 spin columns (Boehringer Mannheim).

Random Primed PCR

Double-stranded cDNA was synthesized from poly A+ RNA isolated from *Arabidopsis* root tissue using the cDNA Synthesis System (GIBCO BRL) with oligo dT12-18 as primers. cDNAs longer than 300 bp were enriched by Sephacryl S-400 column chromatography (Stratagene). Fractionated cDNAs were used as templates for RP-PCR labeling. The reaction contained 10 mM Tris-HCl, ph 9.0, 50 mM KCl, 0.1% Triton X-100, 2 mM MgCl2, 5 units *Taq* DNA polymeras (PROMEGA), 200 µM dCTP, cGTP, and dTTP, and different concentrations of hexamer random primers α-32P dATP, 800 mCi/mmole, 10 mCi/ml (DuPont), and cold dATP in a final volume of 25 µl. After an initial 5 minutes at 95°C, different reactions were run through different programs to optimize RP-PCR cDNA conditions. Unless otherwise indicated, the following program was used for most RP-PCR cDNA probe labeling: 95°C/5 minutes, then 40 cycles of 95°C 30 seconds, 18°C/1 second, ramp to 30°C at a rate of 0.1°C/second. 72°C/1 minute. RP-PCR products were phenol/chloroform extracted and ethanol

precipitated or purified by passing through Sephadex G-50 spin columns (Boehringer Mannheim).

Clone blot virtual subtraction

Mass excision of λ-ZAP cDNA libraries was carried out by co-infecting XL1-Blue MRF' host cells with recombinant phage from the libraries and ExAssist helper phage (STRATAGENE). Excised phagemids were rescued by SOLR cells. Plasmid DNAs were prepared by boiling mini-prep method (Holmes et al. 1981 *Anal. Biochem. 114*:193-197) from randomly isolated clones. cDNA inserts were excised by EcoRI and XhoI double digestion, and resolved on 1% agarose gels. The DNAs were denatured in 0.5 N NaOH and 1.5 m NaCl for 45 minutes, neutralized in 0.5 M Tris-HCl, pH 8.0, and 1.5 M NaCl for 45 minutes, and then transferred by blotting to nylon membranes (Micron Separations, Inc.) in 10X SSC overnight. After one hour prehybridization at 65°C, root RP-cDNA probe was added to the same hybridization buffer containing 1% bovine albumin fraction V (Sigma), 1 mM EDTA, 0.5 M NaHPO4, pH 7.2, 7% SDS. The hybridization continued for 24 hours at 65°C. The filters were washed in 0.5% bovine albumin, 1 mM EDTA, 40 mM NaHPO4, pH 7.2, 5% SDS for ten minutes at room temperature, and 3 x 10 minutes in 1 mM EDTA, 40 mM NaHPO4, pH 7.2, 1% SDS at 65°C. Autoradiographs were exposed to X-ray films (Kodak) for two to five days at -80°C.

Hybridization of resulting blots with root RP-PCR probes "virtually subtracted" seed cDNAs shared

with the root mRNA population. The remaining seed cDNAs representing putative seed-specific cDNAs, including those encoding oleosins, were sequenced by the cycle sequencing method, thereby identifying AtS21 as an oleosin cDNA clone.

Sequence analysis of AtS21

The oleosin cDNA is 834 bp long including an 18 bp long poly A tail (Fig. 4, SEQ ID NO:2) It has high homology to other oleosin genes from *Arabidopsis* as well as from other species. Recently, an identical oleosin gene has been reported (Zou, et al., 1996, *Plant Mol.Biol. 31*:429-433). The predicted protein is 191 amino acids long with a highly hydrophobic middle domain flanked by a hydrophilic domain on each side. The existence of two upstream in frame stop codons and the similarity to other oleosin genes indicate that this cDNA is full-length. Since there are two in frame stop codons just upstream of the first ATG, this cDNA is considered to be a full length cDNA (Figure 4, SEQ ID NO:2). The predicted protein has three distinctive domains based on the distribution of its amino acid residues. Both the N-terminal and C-terminal domains are rich in charged residues while the central domain is absolutely hydrophobic (Figure 5). As many as 20 leucine residues are located in the central domain and arranged as repeats with one leucine occurring every 7-10 residues. Other non-polar amino acid residues are also clustered in the central domain making this domain absolutely hydrophobic (Figure 6).

Extensive searches of different databases using both AtS21 cDNA and its predicted protein sequence identified oleosins from carrot, maize, cotton, rapeseed, *Arabidopsis*, and other plant species. The homology is mainly restricted to the central hydrophobic domain. Seven *Arabidopsis* oleosin sequences were found. AtS21 represents the same gene as Z54164 which has a few more bases in the 5' untranslated region. The seven *Arabidopsis* oleosin sequences available so far were aligned to each other (Figure 7). The result suggested that the seven sequences fall into three groups. The first group includes AtS21 (SEQ ID NO:5), X91918 (SEQ ID NO:6), and the partial sequence Z29859 (SEQ ID NO:7). Since X91918 (SEQ ID NO:6) has only its last residue different from AtS21 (SEQ ID NO:5), and since Z29859 (SEQ ID NO:7) has only three amino acid residues which are different from AtS21 (SEQ ID NO:5), all three sequences likely represent the same gene. The two sequences of the second group, X62352 (SEQ ID NO:8) and Ato13 (SEQ ID NO:9), are different in both sequence and length. Thus, there is no doubt that they represent two independent genes. Like the first group, the two sequences of the third group, X91956 (SEQ ID NO:10) and L40954 (SEQ ID NO:11), also have only three divergent residues which may be due to sequence errors. Thus, X91956 (SEQ ID NO:10) and L40954 (SEQ ID NO:11) likely represent the same gene. Unlike all the other oleosin sequences which were predicted from cDNA sequences, X62352 (SEQ ID NO:8)

was deduced from a genomic sequence (Van Rooigen et al. 1992 *Plant Mol. Biol.* *18*:1177-1179). In conclusion, four different *Arabidopsis* oleosin genes have been identified so far, and they are conserved only in the middle of the hydrophobic domain.

Northern Analysis

In order to characterize the expression pattern of the native AtS21 gene, Northern analysis was performed as described in Example 4 except that the probe was the AtS21 cDNA (pAN1 insert) labeled with ^{32}P-dATP to a specific activity of 5 x 10^8 cpm/ug.

Results indicated that the AtS21 gene is strongly expressed in developing seeds and weakly expressed in silique coats (Figure 8A). A much larger transcript, which might represent unprocessed AtS21 pre-mRNA, was also detected in developing seed RNA. AtS21 was not detected in flower, leaf, root (Figure 8A), or one day silique RNAs. A different Northern analysis revealed that AtS21 is also strongly expressed in imbibed germinating seeds (Figs. 13A and 13B)

EXAMPLE 6

Characterization of Oleosin Genomic Clones and Isolation of Oleosin Promoter

Genomic clones were isolated by screening an *Arabidopsis* genomic DNA library using the full length cDNA (AtS21)as a probe. Two genomic clones were mapped by restriction enzyme digestion followed by Southern hybridization using the 5' half of the cDNA cleaved by SacI as a probe. A 2 kb SacI fragment was subcloned and sequenced (Fig. 9, SEQ ID NO:35). Two regions of the genomic clone are identical to the cDNA sequence. A 395 bp intron separates the two regions.

The copy number of AtS21 gene in the *Arabidopsis* genome was determined by genomic DNA Southern hybridization following digestion with the enzymes BamHI, EcoRI, HindIII, SacI and XbaI, using the full length cDNA as a probe (Figure 8B). A single band was detected in all the lanes except SacI digestion where two bands were detected. Since the cDNA probe has an internal SacI site, these results indicated that AtS21 is a single copy gene in the *Arabidopsis* genome. Since it has been known that Arabidopsis genome contains different isoforms of oleosin genes, this Southern analysis also demonstrates that the different oleosin isoforms of *Arabidopsis* are divergent at the DNA sequence level.

Two regions, separated by a 395 bp intron, of the genomic DNA fragment are identical to AtS21 cDNA sequence. Database searches using the 5' promoter sequence upstream of AtS21 cDNA sequence did

not identify any sequence with significant homology. Furthermore, the comparison of AtS21 promoter sequence with another *Arabidopsis* oleosin promoter isolated previously (Van Rooijen, et al., 1992) revealed little similarity. The AtS21 promoter sequence is rich in A/T bases, and contains as many as 44 direct repeats ranging from 10 bp to 14 bp with only one mismatch allowed. Two 14 bp direct repeats, and a putative ABA response element are underlined in Figure 9.

EXAMPLE 7

Construction of AtS21 Promoter/GUS Gene Expression Cassette and Expression Patterns in Transgenic *Arabidopsis* and Tobacco

Construction of AtS21 promoter/GUS gene expression cassette

The 1267 bp promoter fragment starting from the first G upstream of the ATG codon of the genomic DNA fragment was amplified using PCR and fused to the GUS reporter gene for analysis of its activity. The promoter fragment of the AtS21 genomic clone was amplified by PCR using the T7 primer GTAATACGACTCACTATAGGGC (SEQ ID NO:13) and the 21P primer GGGGATCCTATACTAAAACTATAGAGTAAAGG (SEQ ID NO:14) complementary to the 5' untranslated region upstream of the first ATG codon (Figure 9). A BamHI cloning site was introduced by the 21P primer. The amplified fragment was cloned into the BamHI and SacI sites of pBluescript KS (Stratagene). Individual clones were sequenced to check possible PCR mutations as well as the orientation of their inserts. The correct clone was digested with BamHI and HindIII, and the excised promoter fragment (1.3 kb) was cloned into the corresponding sites of pBI101.1 (Jefferson, R.A. 1987a, *Plant Mol. Biol. Rep.* 5:387-405; Jefferson et al., 1987b, *EMBO J.* 6:3901-3907) upstream of the GUS gene. The resultant plasmid was designated pAN5 (Fig. 10). The AtS21 promoter/GUS construct (pAN5) was introduced into both tobacco (by the leaf disc method, Horsch et al., 1985; Bogue et al. 1990 *Mol. Gen. Gen.*

221:49-57) and *Arabidopsis* Colombia ecotype via vacuum infiltration as described by Bechtold, et al. (1993) *C.R. Acad. Sci. Paris, 316:*1194-1199. Seeds were sterilized and selected on media containing 50 μg/ml kanamycin, 500 μg/ml carbenicillin.

GUS activity assay: Expression patterns of the reporter GUS gene were revealed by histochemical staining (Jefferson, et al., 1987a, *Plant Mol. Biol. Rep.* 5:387-405). Different tissues were stained in substrate solution containing 2 mg/ml 5-bromo-4-chloro-3-indolyl-β-D-glucuronic acid (X-Gluc) (Research Organics, Inc.), 0.5 mM potassium ferrocyanide, and 0.5 mM potassium ferricyanide in 50 mM sodium phosphate buffer, pH 7.0 at 37°C overnight, and then dehydrated successively in 20%, 40% and 80% ethanol (Jefferson, et al., 1987). Photographs were taken using an Axiophot (Zeiss) compound microscope or Olympus SZH10 dissecting microscope. Slides were converted to digital images using a Spring/Scan 35LE slide scanner (Polaroid) and compiled using Adobe Photoshop™ 3.0.5 and Canvas™ 3.5.

GUS activities were quantitatively measured by fluorometry using 2 mM 4-MUG (4-methylumbelliferyl-β-D-glucuronide) as substrate (Jefferson, et al., 1987). Developing *Arabidopsis* seeds were staged according to their colors, and other plant tissues were collected and kept at -80°C until use. Plant tissues were ground in extraction buffer containing 50 mM sodium phosphate, pH 7.0, 10 mM EDTA, 10 mM β-mercaptoethanol, 0.1% Triton X-100, and 0.1% sodium

lauryl sarcosine. The tissue debris was removed by 5 minutes centrifugation in a microfuge. The supernatant was aliquoted and mixed with substrate and incubated at 37°C for 1 hour. Three replicas were assayed for each sample. The reactions were stopped by adding 4 volumes of 0.2 M sodium carbonate. Fluorescence was read using a TKO-100 DNA fluorometer (Hoefer Scientific Instruments). Protein concentrations of the extracts were determined by the Bradford method (Bio Rad).

Expression patterns of AtS21 promoter/GUS in transgenic *Arabidopsis* and tobacco

In *Arabidopsis*, GUS activity was detected in green seeds, and node regions where siliques, cauline leaves and branches join the inflorescence stem (Figures 11A and 11B). No GUS activity was detected in any leaf, root, flower, silique coat, or the internode regions of the inflorescence stem. Detailed studies of the GUS expression in developing seeds revealed that the AtS21 promoter was only active in green seeds in which the embryos had already developed beyond heart stage (Figures 11C and 11G). The youngest embryos showing GUS activity that could be detected by histochemical staining were at early torpedo stage. Interestingly, the staining was only restricted to the lower part of the embryo including hypocotyl and embryonic radical. No staining was detected in the young cotyledons (Figures 11D and 11E). Cotyledons began to be stained when the embryos

were at late torpedo or even early cotyledon stage (Figure 11F and 11H). Later, the entire embryos were stained, and the staining became more intense as the embryos matured (Figures 11I and 11J). It was also observed that GUS gene expression was restricted to the embryos. Seed coat and young endosperm were not stained (Figure 11C).

GUS activity was also detected in developing seedlings. Young seedlings of 3-5 days old were stained everywhere. Although some root hairs close to the hypocotyl were stained (Figure 11K), most of the newly formed structures such as root hairs, lateral root primordia and shoot apex were not stained (Figures 11L and 11N). Later, the staining was restricted to cotyledons and hypocotyls when lateral roots grew from the elongating embryonic root. The staining on embryonic roots disappeared. No staining was observed on newly formed lateral roots, true leaves nor trichomes on true leaves (Figures 11M and 11N).

AtS21 promoter/GUS expression patterns in tobacco are basically the same as in *Arabidopsis*. GUS activity was only detected in late stage seeds and different node regions of mature plants. In germinating seeds, strong staining was detected throughout the entire embryos as soon as one hour after they were dissected from imbibed seeds. Mature endosperm, which *Arabidopsis* seeds do not have, but not seed coat was also stained (Figure 12A). The root tips of some young seedlings of one transgenic line

were not stained (Figure 12B). Otherwise, GUS expression patterns in developing tobacco seedlings were the same as in *Arabidopsis* seedlings (Figures 12B, 12C, and 12D). Newly formed structures such as lateral roots and true leaves were not stained.

AtS21 mRNA levels in developing seedlings

Since the observed strong activities of AtS21 promoter/GUS in both *Arabidopsis* and tobacco seedlings are not consistent with the seed-specific expression of oleosin genes, Northern analysis was carried out to determine if AtS21 mRNA was present in developing seedlings where the GUS activity was so strong. RNAs prepared from seedlings at different stages from 24 hours to 12 days were analyzed by Northern hybridization using AtS21 cDNA as the probe. Surprisingly, AtS21 mRNA was detected at a high level comparable to that in developing seeds in 24-48 hour imbibed seeds. The mRNA level dropped dramatically when young seedlings first emerged at 74 hours (Figures 13A and 13B). In 96 hour and older seedlings, no signal was detected even with a longer exposure (Figure 13B). The loadings of RNA samples were checked by hybridizing the same blot with a tubulin gene probe (Figure 13C) which was isolated and identified by EST analysis as described in Example 2. Since AtS21 mRNA was so abundant in seeds, residual AtS21 probes remained on the blot even after extensive stripping. These results indicated that AtS21 mRNA detected in imbibed seeds and very young seedlings are

the carry-over of AtS21 mRNA from dry seeds. It has recently been reported that an oleosin Atol2 mRNA (identical to AtS21) is most abundant in dry seeds (Kirik, et al., 1996 *Plant Mol. Biol. 31(2)*:413-417.) Similarly, the strong GUS activities in seedlings were most likely due to the carry-over of both β-glucuronidase protein and the *de novo* synthesis of β-glucuronidase from its mRNA carried over from the dry seed stage.

EXAMPLE 8

Activity comparison between the AtS21 promoter and the 35S promoter

The GUS activities in transgenic *Arabidopsis* developing seeds expressed by the AtS21 promoter were compared with those expressed by the 35S promoter in the construct pBI221 (Jefferson et al. *EMBO J. 6*:3901-3907). The seeds were staged according to their colors (Table 2). The earliest stage was from globular to late heart stage when the seeds were still white but large enough to be dissected from the siliques. AtS21 promoter activity was detected at a level about three times lower than that of the 35S promoter at this stage. 35S promoter activity remained at the same low level throughout the entire embryo development. In contrast, AtS21 promoter activity increased quickly as the embryos passed torpedo stage and reached the highest level of 25.25 pmole 4-MU/min. μg protein at mature stage (Figure 5-8). The peak activity of the AtS21 promoter is as much as 210 times higher than its lowest activity at globular to heart stage, and is close to 100 times higher than the 35S promoter activity at the same stage (Table 2). The activity levels of the AtS21 promoter are similar to those of another *Arabidopsis* oleosin promoter expressed in *Brassica napus* (Plant et al. 1994, *Plant mol. Biol. 25*:193-205. AtS21 promoter activity was also detected at background level in leaf. The high standard deviation, higher than the average itself, indicated that the GUS activity was

only detected in the leaves of some lines (Table 2). On the other hand, 35S promoter activity in leaf was more than 20 times higher than that in seed. The side by side comparisons of activities between AtS21 promoter and 35S promoter is shown in Figure 14.

Although the AtS21 promoter activity was about 3 times lower in dry seed of tobacco than in *Arabidopsis* dry seed, the absolute GUS activity was still higher than that expressed by the 35S promoter in *Arabidopsis* leaf (Table 2). No detectable AtS21 promoter activity was observed in tobacco leaf (Figure 14).

Comparison of the AtS21 promoter versus the 35S promoter revealed that the latter is not a good promoter to express genes at high levels in developing seeds. Because of its consistent low activities throughout the entire embryo development period, 35S promoter is useful for consistent low level expression of target genes. On the other hand, the AtS21 promoter is a very strong promoter that can be used to express genes starting from heart stage embryos and accumulating until the dry seed stage. The 35S promoter, although not efficient, is better than the AtS21 promoter in expressing genes in embryos prior to heart stage.

TABLE 2

GUS ACTIVITIES OF AtS21 and 35S PROMOTER/GUS CONSTRUCTS

COLOR STAGE	WHITE G-H	WHITE/YELLOW H-T	YELLOW T-C	LIGHT GREEN EARLY C	DARK GREEN LATE C	GREEN/YELLOW/BROWN MATURE	BROWN DRY SEED	LEA:
AtS21	0.12±0.17	1.35±1.57	6.77±1.25	18.99±3.75	21.85±4.45	25.25±4.64	24.38±10.85	0.08±0.
35S	0.30±0.06	0.25±0.08	0.29±0.04	0.28±0.03	0.33±0.06	0.26±0.04	0.31±0.02	6.56±0.
AtS21	(In tobacco)						8.81±0.21	0.01±0.

Abbreviations: G, globular stage; H, heart stage; T, torpedo stage; C, cotyledon stage. The GUS activities are in pmole 4-MU/μg protein.min. For AtS21 promoter the numbers are the average of five independent lines with standard deviations. Three repeats were assayed for each line. For 35S promoter the numbers are the average of three repeats of the same line with standard deviations.

EXAMPLE 9

Expression of the Borage Δ^6-Desaturase Gene Under the Control of the AtS21 Promoter and Comparison to Expression Under the Control of the CaMV 35S Promoter

In order to create an expression construct with the AtS21 promoter driving expression of the borage $\Delta6$-desaturase gene, the GUS coding fragment from pAN5 was removed by digestion with SmaI and EcoICR I. The cDNA insert of pAN1 (Example 2)was then excised by first digesting with XhoI (and filling in the residual overhang as above), and then digesting with SmaI. The resulting fragment was used to replace the excised portion of pAN5, yielding pAN3.

After transformation of tobacco and *Arabidopsis* following the methods of Example 7, levels of Δ^6-desaturase activity were monitored by assaying the corresponding fatty acid methyl esters of its reaction products, γ-linolenic acid (GLA) and octadecatetraenoic acid (OTA) using the methods referred to in Example 3. The GLA and OTA levels (Table 3) of the transgenic seeds ranged up to 6.7% of C18 fatty acids (Mean = 3.1%) and 2.8% (Mean = 1.1%), respectively. No GLA or OTA was detected in the leaves of these plants. In comparison, CaMV 35 S promoter/Δ^6-desaturase transgenic plants produced GLA levels in seeds ranging up to 3.1% of C18 fatty acids (Mean = 1.3%) and no measurable OTA in seeds.

TABLE 3

EXPRESSION OF THE BORAGE Δ^6-DESATURASE IN TRANSGENIC PLANTS

EXAMPLE 10

Transformation of Oilseed Rape With an Expression Cassette Which Comprises the Oleosin 5' Regulatory Region Linked to the Borage Delta 6-Desaturase Gene

Oilseed rape, Cv. Westar, was transformed with the strain of *Agrobacterium tumefaciens* EHA105 containing the plasmid pAN3 (i.e. the borage Δ6-desaturase gene under the control of the *Arabidopsis* oleosin promoter-Example 9).

Terminal internodes of Westar were co-cultivated for 2-3 days with induced *Agrobacterium tumefaciens* strain EHA105 (Alt-Moerbe et al. 1988 *Mol. Gen. Genet.* 213:1-8; James et al. 1993 *Plant Cell Reports* 12:559-563), then transferred onto regeneration medium (Boulter etal. 1990 *Plant Science* 70:91-99; Fry et al. 1987 *Plant Cell Reports* 6:321-325). The regenerated shoots were transferred to growth medium (Pelletier et al. 1983 *Mol.Gen. Menet.* 191:244-250), and a polymerase chain reaction (PCR) test was performed on leaf fragments to assess the presence of the gene.

DNA was isolated from the leaves according to the protocol of KM Haymes et al. (1996) *Plant Molecular Biology Reporter* 14(3):280-284, and resuspended in 100µl of water, without RNase treatment. 5µl of extract were used for the PCR reaction, in a final volume of 50µl. The reaction was performed in a Perkin-Elmer 9600 thermocycler, with the following cycles:

1 cycle: 95°C, 5 minutes
30 cycles: 95°C, 45 sec; 52°C, 45 sec
72°C, 1 minute

1 cycle: 72°C, 5 minutes

and the following primers (derived from near the metal box regions, as indicated in Fig. 1, SEQ. NO.:1):
5' TGG AAA TGG AAC CAT AA 3'
5' GGA AAC AAA TGA TGC TC 3'
Amplification of the DNA revealed the expected 549 base pair PCR fragment (Figure 17).

The positive shoots were transferred to elongation medium, then to rooting medium (DeBlock et al 1989 *Plant Physiol.* 91:694-701).Shoots with a well-developed root system were transferred to the greenhouse. When plants were well developed, leaves were collected for Southern analysis in order to assess gene copy number.

Genomic DNA was extracted according to the procedure of Bouchez et al. (1996) *Plant Molecular Biology Reporter* 14:115-123, digested with the restriction enzymes *Bgl* I and/or *Cla* I, electrophoretically separated on agarose gel (Maniatis et al. 1982, in *Molecular Cloning; a Laboratory Manual. Cold Spring Harbor Laboratory Press, Cold Spring Harbor/NY*), and prepared for transfer to nylon membranes (Nytran membrane, Schleicher & Schuell) according to the instructions of the manufacturer. DNA was then transferred to membranes overnight by capillary action using 20XSSC (Maniatis et al. 1982).

Following transfer, the membranes were crosslinked by UV (Stratagene) for 30 seconds and pre-hybridized for 1 hour at 65°C in 15 ml of a solution containing 6XSSC, 0.5%SDS and 2.25% w/w dehydrated skim milk in glass vials in hybridization oven (Appligene). The membranes were hybridized overnight in the same solution containing a denatured hybridization probe radiolabelled with ^{32}P to a specific activity of 10^8 cpm/µg by the random primer method (with the Ready-To-Go kit obtained from Pharmacia). The probe represents a PCR fragment of the borage delta 6-desaturase gene (obtained in the conditions and with the primers detailed above). After hybridization, the filters were washed at 65°C in 2XSSC, 0.1% SDS for 15 minutes, and 0.2XSSC, 0.1%SDS for 15 minutes. The membranes were then wrapped in Saran-Wrap and exposed to Kodak XAR film using an intensifying screen at -70°C in a light-proof cassette. Exposure time was generally 3 days.

The results obtained confirm the presence of the gene. According to the gene construct, the number of bands in each lane of DNA digested by *Bgl* I or *Cla* I represents the number of delta 6-desaturase genes present in the genomic DNA of the plant. The digestion with *Bgl* 1 and *Cla* 1 together generates a fragment of 3435 bp.

The term "comprises" or "comprising" is defined as specifying the presence of the stated features, integers, steps, or components as referred to in the claims, but does not preclude the presence or addition of one or more other features, integers, steps, components, or groups thereof.

What is claimed is:

1. An isolated nucleic acid encoding an oleosin 5' regulatory region which directs seed-specific expression selected from the groups consisting of the nucleotide sequence set forth in SEQ ID NO:12, the nucleotide sequence set forth in SEQ ID NO:12 having an insertion, deletion, or substitution of one or more nucleotides, or a contiguous fragment of the nucleotide sequence set forth in SEQ ID NO:12.

2. An expression cassette which comprises the oleosin 5' regulatory region of Claim 1 operably linked to at least one of a nucleic acid encoding a heterologous gene or a nucleic acid encoding a sequence complementary to a native plant gene.

3. The expression cassette of Claim 2 wherein the heterologous gene is at least one of a fatty acid synthesis gene or a lipid metabolism gene.

4. The expression cassette of Claim 3 wherein the heterologous gene is selected from the group consisting of an acetyl-coA carboxylase gene, a ketoacyl synthase gene, a malonyl transacylase gene, a lipid desaturase gene, an acyl carrier protein (ACP) gene, a thioesterase gene, an acetyl transacylase gene, or an elongase gene.

5. The expression cassette of Claim 4 wherein the lipid desaturase gene is selected from the group consisting of a $\Delta6$-desaturase gene, a $\Delta12$-desaturase gene, and a $\Delta15$-desaturase gene.

6. An expression vector which comprises the expression cassette of any one of Claims 2-5.

7. A cell comprising the expression cassette of any one of Claims 2-5.

8. A cell comprising the expression vector of Claim 6.

9. The cell of Claim 7 wherein said cell is a bacterial cell or a plant cell.

10. The cell of Claim 8 wherein said cell is a bacterial cell or a plant cell.

11. A transgenic plant comprising the expression cassette of any one of Claims 2-5.

12. A transgenic plant comprising the expression vector of Claim 6.

13. A plant which has been regenerated from the plant cell of Claim 9.

14. A plant which has been regenerated from the plant cell of Claim 10.

15. The plant of Claim 12 or 13 wherein said plant is at least one of a sunflower, soybean, maize, cotton, tobacco, peanut, oil seed rape or *Arabidopisis* plant.

16. Progeny of the plant of Claim 11 or 12.

17. Seed from the plant of Claim 11 or 12.

18. A method of producing a plant with increased levels of a product of a fatty acid synthesis gene or a lipid metabolism gene which comprises:

(a) transforming a plant cell with an expression vector comprising the isolated nucleic acid of Claim 1 operably linked to at least one of an

isolated nucleic acid coding for a fatty acid synthesis gene or a lipid metabolism gene; and

(b) regenerating a plant with increased levels of the product of said fatty acid synthesis or said lipid metabolism gene from said plant cell.

19. A method of producing a plant with increased levels of gamma linolenic acid (GLA) content which comprises:

(a) transforming a plant cell with an expression vector comprising the isolated nucleic acid of Claim 1 operably linked to a Δ6-desaturase gene; and

(b) regenerating a plant with increased levels of GLA from said plant cell.

20. The method of Claim 19 wherein said Δ6-desaturase gene is at least one of a cyanobacterial Δ6-desaturase gene or a Borage Δ6-desaturase gene.

21. The method of any one of Claims 18-20 wherein said plant is a sunflower, soybean, maize, tobacco, cotton, peanut, oil seed rape or *Arabidopsis* plant.

22. The method of Claim 18 wherein said fatty acid synthesis gene or said lipid metabolism gene is at least one of a lipid desaturase, an acyl carrier protein (ACP) gene, a thioesterase gene an elongase gene, an acetyl transacylase gene, an acetyl-coA carboxylase gene, a ketoacyl synthase gene, or a malonyl transacylase gene.

23. A method of inducing production of at least one of gamma linolenic acid (GLA) or

octadecatetraeonic acid (OTA) in a plant deficient or lacking in GLA which comprises transforming said plant with an expression vector comprising an the isolated nucleic acid of Claim 1 operably linked to a Δ6-desaturase gene and regenerating a plant with increased levels of at least one of GLA or OTA.

24. A method of decreasing production of a fatty acid synthesis or lipid metabolism gene in a plant which comprises:

(a) transforming a plant cell with an expression vector comprising the isolated nucleic acid of Claim 1 operably linked to a nucleic acid sequence complementary to a fatty acid synthesis or lipid metabolism gene; and

(b) regenerating a plant with decreased production of said fatty acid synthesis or said lipid metabolism gene.

25. A method of cosuppressing a native fatty acid synthesis or lipid metabolism gene in a plant which comprises:

(a) transforming a cell of the plant with an expression vector comprising the isolated nucleic acid of Claim 1 operably linked to a nucleic acid sequence encoding a fatty acid synthesis or lipid metabolism gene native to the plant; and

(b) regenerating a plant with decreased production of said fatty acid synthesis or said lipid metabolism gene.

Molecular Cloning and Functional Characterization of Rat Δ-6 Fatty Acid Desaturase

Tsunehiro Aki,[1] Yayoi Shimada, Katsuya Inagaki, Hirofumi Higashimoto, Seiji Kawamoto, Seiko Shigeta, Kazuhisa Ono, and Osamu Suzuki

Department of Molecular Biotechnology, Hiroshima University, 1-4-1 Kagamiyama, Higashi-Hiroshima 739-8527, Japan

Received January 6,1999

Mammalian cDNA fragments putatively encoding amino acid sequences characteristic of the fatty acid desaturase were obtained using expressed sequence tag (EST) sequence informations. These fragments were subsequently used to screen a rat liver cDNA library, yielding a 1573-bp clone. Expression of DNA fragment containing either of two possible open reading frames (nucleotide numbers 97-1431 and 148-1431) of the isolated clone in yeast led to the accumulation of γ-linolenic acid in the presence of exogenous linoleic acid. In this system, the addition of α-linolenic acid also resulted in the accumulation of its Δ-6 desaturated product whereas dihomo-γ-linolenic acid failed to be a substrate. These results indicate that the protein encoded by the rat cDNA is Δ-6 fatty acid desaturase, and the first 17 amino acids corresponding to the coding region 97-147 of the clone are not required to function in yeast. © 1999 Academic Press

Δ-6 Desaturase catalyzes the conversion of linoleic acid (LA, C18:2Δ-9, 12) to γ-linolenic acid (GLA, C18:3Δ-6, 9, 12) by inserting a double bond between carbon 6 and 7, in conjunction with cytochrome b_5-mediated electron transfer system in mammals. Since GLA and its elongation product, dihomo-γ-linolenic acid (DGLA, C20:3Δ-8, 11, 14), are barely detectable in mammalian cells, it is generally accepted that the Δ-6 desaturation step is rate-limiting (1). In this context, the activity of the Δ-6 desaturase is considered to affect directly to the cellular content of arachidonic acid (AA, C20:4Δ-5, 8, 11, 14) which is a Δ-5 desaturated product of DGLA. It is feasible to extend this aspects on the n-6 pathway to another pathway (n-3) where α-linolenic acid (ALA, C18:3Δ-9, 12, 15) is converted to eicosapentaenoic acid (EPA, C20:5Δ-5, 8, 11, 14, 17) through Δ-6 desaturation.

AA is well-known as a precursor of a large family of eicosanoids that have multiple effects related to the regulation of e.g. blood pressure, inflammatory reactions, and platelet function (1–3). EPA exhibits antagonizing effect aganst AA metabolism, and *vise versa* (4, 5). Since the amounts and types of eicosanoids synthesized are partially determined by the availability of the fatty acid precursors, imbalance of these acids is suggested to contribute to numerous clinical symptoms. An early study indicated that affinity of the Δ-6 desaturase for ALA is greater than that for LA, implying that these fatty acids might not be metabolized in the same fashion (6). Therefore, the imbalance of the levels of fatty acid precursors could be due to the impaired activity of the Δ-6 desaturase on either of the two pathways. Indeed, depression of the Δ-6 desaturase activity, mainly reported on the n-6 pathway, is associated with various physiologic and pathophysiologic states including aging, diabetes, atopic dermatitis, cardiovascular disorders, and cancer (1, 7, 8). Also, the differences in nutritional and hormonal conditions influence the Δ-6 desaturase activity, resulting in the altered composition of intracellular fatty acids and membrane phospholipids (1, 9). Up to now, these observations have been led, in part, by tracing the activity of the enzyme, detected predominantly in the microsomal membrane fraction. However, molecular characterization of the membrane-bound desaturase protein especially in mammals has not been fully established.

Recently, genes coding for Δ-6 desaturases from the borage *Borago officinalis* (10) and the nematode *Caenorhabditis elegans* (11) and Δ-5 desaturases from *C. elegans* (12) and the fungus *Mortierella alpina* (13, 14) were identified. Mutual comparisons of their deduced amino acid sequences revealed the presence of highly conserved heme-binding motif and histidine boxes, located in same order, which appeared to be common in all desaturases of bacteria and plants (15). Taking advantage of the sequence informations on the desaturases in eukaryotes, we newly identified a rat liver

0006-291X/99 $30.00

cDNA encoding functional Δ-6 fatty acid desaturase, as reported here.

MATERIALS AND METHODS

General laboratory chemicals were purchased from Katayama Chemical (Osaka, Japan). Fatty acid standards were from Sigma Chemical Co. (St. Louis, MO). Reagents and enzymes for genetic manipulations were from Takara Shuzo (Kyoto, Japan), otherwise stated. Male BALB/c mice were obtained from Charles River Japan (Hiroshima, Japan).

Messenger RNAs were extracted from mouse liver by guanidinium thiocyanate method using QuickPrep mRNA Purification Kit (Amersham Pharmacia Biotech, Uppsala, Sweden). A cDNA pool was prepared from the mouse mRNAs by TimeSaver cDNA Synthesis Kit (Amersham Pharmacia Biotech) according to the manufacturer's instruction. Oligonucleotide primers of following sequences were synthesized for amplification of two apart regions of gene coding for desaturase-like protein by polymerase chain reaction (PCR); m3F, 5'-GTCAGGGTGCTGGAGAGCCACTGG-3'; m3R, 5'-GTAGTGTAGGCCGTGCTTCGCGC-3'; m5F, 5'-GATGCTACGGATGCCTTCCGTGC[illegible] m5R, 5'-TTCATGTCCTCAGCAGTCTTCTTC-3'. The cDNA fro[illegible]use liver was subjected to PCR reactions (LA PCR kit, Takara) with primer pairs, m3F and m3R, or m5F and m5R. Successfully amplified products, m3 and m5 respectively, were cloned on plasmid pGEM-T Easy Vector (Promega, Madison, WI), and the inserts were confirmed by DNA sequencing analyses.

Rat liver cDNA library constructed on λZAP II (#937507, Stratagene, La Jolla, CA) was probed with alkaline phosphatase-labeled m3 or m5 fragment, by which labeling of the probes, hybridization, and detection of hybrids were performed using AlkPhos Direct System (Amersham Pharmacia Biotech). In this protocol, hybridization and washing steps were done at 55°C. Plaques positively detected by either of the two probes were picked up, and the accuracy of the first screening was reevaluated with purified plaques by another round of plating and hybridization. The plasmids containing positive cDNA were recovered from selected λ clones by *in vivo* excision, and the insert was entirely sequenced on both strands of DNA.

Since one of the positive clones, r24, seemed to contain full-length cDNA of interest, a plasmid derived from clone r24 was used as a template for PCR amplification of regions which were deduced as open reading frames. Because two ATG sequences could be considered as putative translation initiation codons, two forward primers, r24aF, 5'-ACAAAGCTT**ATG**GGGAAGGGAGGTAACCAG-3' (corresponding to the first ATG indicated by boldface type) and r24bF, 5'-C[illegible]AAGCTT**ATG**CCCACCTTCCGCTGGGAG-3' (corresponding to t[illegible]econd ATG indicated by boldface type) were used to amplify the coding frames, r24a and r24b, respectively, and to generate *Hin* dIII site (underlined) adjucent to the ATG. A reverse primer r24R, 5'-TCTTCTAGA**TCA**TTTGTGGAGGTAGGCATC-3' (annealing to the complement of the stop codon indicated by boldface type) was used for each PCR reaction, generating *Xba* I site (underlined). The PCR products treated with *Hin* dIII and *Xba* I were inserted respectively to the yeast vector pYES2 (Invitrogen, San Diego, CA). It was confirmed by DNA sequencing analyses that the entire and flanking sequences of the inserts were as we designed. Transfer of the constructs into *Saccharomyces cerevisiae* strain INVSc1 (Invitrogen) was done by the lithium acetate method, and recombinant yeast cells were selected on uracil-deficient medium. The yeast cells were cultivated in a medium containing 4% raffinose, 0.7% yeast nitrogen base without amino acid, 1% tergitol type NP-40, 20 μg/ml histidine, 60 μg/ml leucine, and 40 μg/ml tryptophan at 28°C, overnight. The culture broth was supplemented with fatty acid substrate so as to be a final concentration of 0.5 mM, followed by further cultivation until cell density reached at 5×10^6 cells/ml. The expression of the transgene was performed by the addition of galactose to 2% (w/v) and an additional cultivation for 10 hr.

Culture broths were harvested, and total intracellular lipids were extracted with a mixture of chloroform/methanol (2:1, v/v). The lipid fraction was subjected to methyl-esterification with 10% hydrochloride in methanol. Fatty acid methyl esters were applied on a gas-liquid chromatograph (GC; model GC-17A, Shimadzu, Kyoto, Japan) equipped with a TC-70 capillary column (GL Science, Tokyo, Japan) and a flame ionization detector. The condition for GC analysis was as previously described (16). GC-mass spectrometry (GC-MS) analysis of the fatty acid methyl esters was performed using a MS-BU20 (JEOL, Tokyo, Japan) high-resolution mass spectrometer linked to a gas chromatograph (model MS-5890, Hewlett Packard) equipped with the TC-70 column as the sample inlet, and operated in the electron impact mode at 70 eV. Comparison of the mass spectra of authentic standards and interest peaks in total ion chromatogram was done by visual- and computer-based examinations.

RESULTS

A nucleotide sequence corresponding to the highly conserved region (indicated by dotted line in Fig. 1) in Δ-6 desaturase from *C. elegans* (11) was used as a query to search databases for related sequences in mammals. When the database of mouse expressed sequence tag (EST) at DNA Data Bank of Japan was searched using both the BLAST and FASTA algorithms, several entries registering DNA sequences partially homologous to the query were retrieved. The nucleotide sequence in 5'-region of one (GenBank accession number W53753) of the ESTs was then used to further search the database and found to be partially overlapped with another EST clone (AA512429). By similar sequential searchs toward 5'-end of a putative desaturase gene in mouse, a clone (AA036321) overlapped with the AA512429 was found, and the AA036321 led us to an additional clone (AA250162). Nucleotide sequence of the AA250162 could be translated to the amino acid sequence bearing partial resemblance to that of N-terminal domain of previously characterized desaturases.

Based on the sequence informations from ESTs W53753 and AA250162, we made two non-overlapping DNA fragments, m3 (3'-region) and m5 (5'-region), respectively, by PCR with a mouse liver cDNA pool as a template. These fragments were used as hybridization probes for isolation of entire coding region of desaturase gene from rat liver cDNA library. We elected rat, instead of mouse, as a source of the target gene, because the desaturases had been best-characterized biochemically in rat, which included a report of partial purification of linoleoyl-CoA desaturase (17; see Discussion). The condition for hybridization was set at medium stringency making allowance for differences in animal species. As a result of screening, five individual clones were isolated as positives to the probe m3 and only one of them, termed r24, was hybridized also with m5 probe. Sequencing of these clones revealed that the clone r24 had a cDNA insert of 1573 basepairs (bp) in length (GenBank accession number AB021980), and

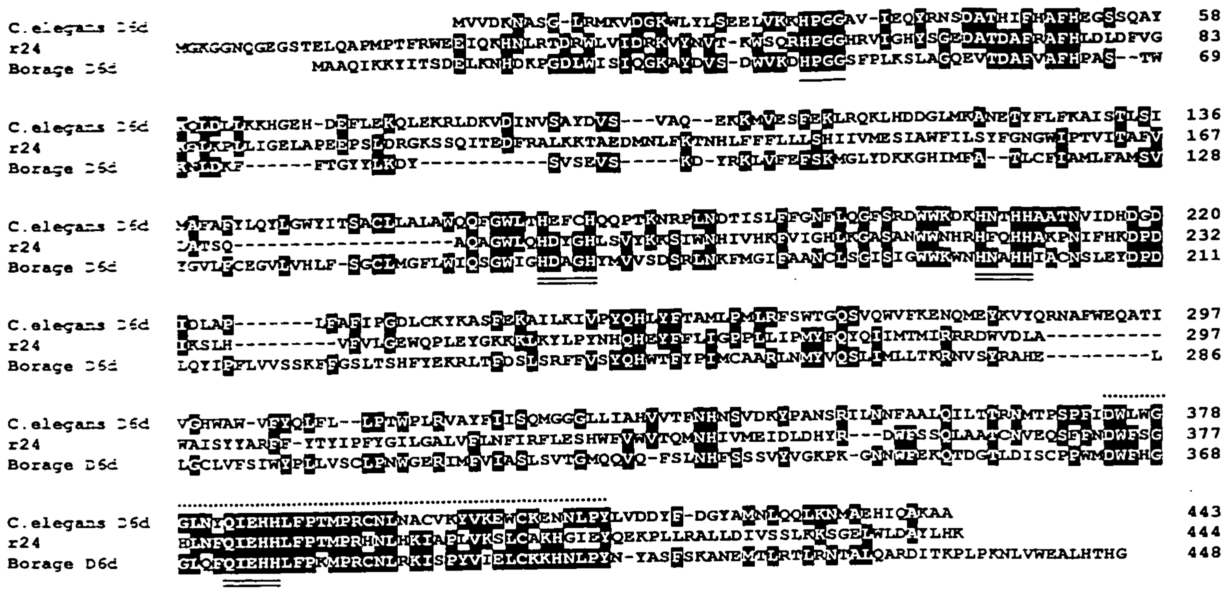

FIG. 1. Composite alignments of the amino acid sequence deduced from the rat cDNA clone r24 with Δ-6 desaturases from other sources. Borage D6d, *B. officinalis* Δ-6 desaturase (GenBank accession number U79010); C.elegans D6d, *C. elegans* Δ-6 desaturase (AF031477). Nucleotide sequence corresponding to the highly conserved region (indicated by dotted line above the sequences) in *C. elegans* Δ-6 desaturase was used as a query to search databases, as mentioned in the text. Identical residues are boxed, and the conserved heme-binding motif and three histidine boxes are marked with single and double underlines, respectively.

cDNAs in remaining four clones (all of them are less than 500 bp in length) were corresponded to 3′-region of r24 (data not shown), supporting the failure of hybridizing with probe m5. A putative protein encoded by the clone r24 seemed to be a rat homolog of the protein from the mouse EST AA250162 (96.5% identity in 491 nucleotides overlap). Thus, we chose the clone r24 for further characterization.

Two ATG initiation codons (nucleotide numbers 97-99 and 148-150) were found in the sequence of 5′-terminal domain of the r24 cDNA and those were placed in-frame. According to the Kozak consensus sequence, AGXXATGG, that has been advocated as favored sequence for eukaryotic initiation sites (18), the first of the two initiation codons is credible. If this is the case, the cDNA contains a coding frame of 1335-bp long including a TGA termination codon (nucleotide numbers 1429-1431), which can be translated into 444 amino acid polypeptide. Comparisons of the deduced amino acid sequence of r24 with Δ-6 desaturases from *C. elegans* and *B. officinalis* showed homology scores of 27.9% and 26.4%, respectively (Fig. 1). It is noted in Fig. 1 that a typical heme-binding motif, HPGG (19), and three histidine boxes highly conserved within fatty acid desaturases (15) are present in the r24 sequence as well as the others. At the third histidine box, the first histidine residue in the conventional motif, HXXHH, was substituted with glutamine. This variance had occured in Δ-6 and Δ-5 desaturases from fungus, plant, and lower animal (10–14).

For functional analysis of the clone r24, two possible coding regions, named r24a and r24b (nucleotide numbers 97-1431 and 148-1431, respectively) were amplified by PCR, and respective expression plasmids were constructed on the yeast vector pYES2. The PCR products were located at just downstream of the galactose-inducible *GAL1* promoter on each construct. After obtaining yeast transformants carrying pYES2/r24a, pYES2/r24b, or pYES2 (control), cells were cultivated, supplemented by the addition of substrate LA (C18:2Δ-9, 12), and induced in the presence of galactose. Aliquots of cells in the induced culture broth were taken for analyses of the intracellular fatty acid composition by GC, and the resultant chromatograms of fatty acid methyl esters were shown as Fig. 2. A novel peak, which was not apparent in the case of control (Fig. 2A), was detected in charts from both induced pYES2/r24a (peak 6 in Fig. 2B) and pYES2/r24b (data not shown). Similarly, when the substrate LA was replaced with ALA (C18:3Δ-9, 12, 15), a peak additional to the background level in the control case (Fig. 2C) was found in a GC profile obtained from the yeast transformed with either pYES2/r24a (peak 8 in Fig. 2D) or pYES2/r24b (data not shown). We confirmed that these and other additional peaks did not appear when the yeast carrying pYES2/r24a or pYES2/r24b was not induced by galactose or was supplemented with none of exogenous fatty acids. Comparisons of the retention times of the newly yielded peaks with those of authentic standards have anticipated that the fatty

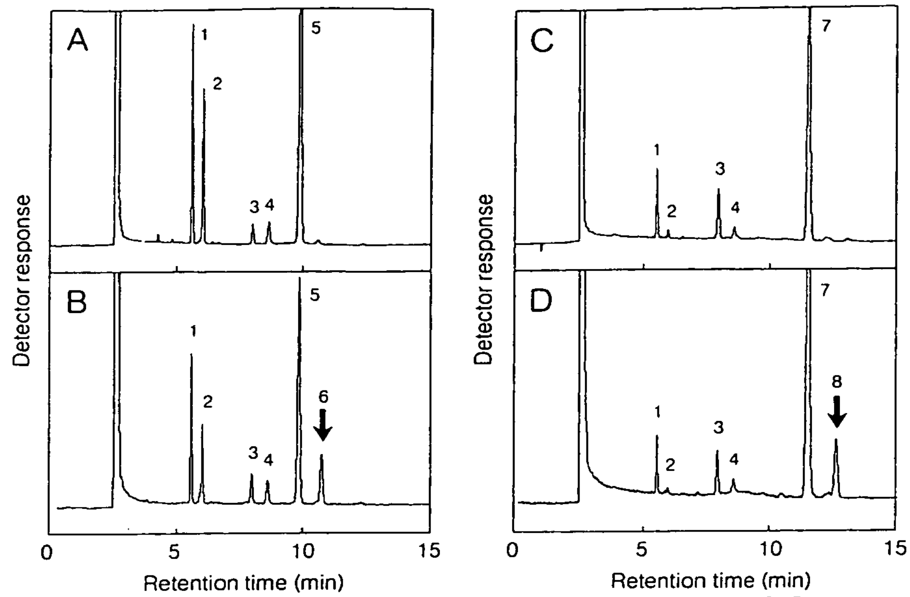

FIG. 2. GC analyses of methyl esterified fatty acids from the induced yeast cells containing pYES2 (A and C) or pYES2/r24a (B and D). Before the induction with galactose, LA (peak 5 in A and B) or ALA (peak 7 in C and D) was added to be incorporated to the cells. The peaks that found only in the case of pYES2/r24a were indicated by arrows (peak 6 in B and peak 8 in D). Identities of other peaks were determined by comparing their retention times with those of authentic standards. Peaks 1, C16:0; 2, C16:1Δ-9; 3, C18:0; 4, C18:1Δ-9.

acids giving the peaks 6 and 8 are GLA (C18:3Δ-6, 9, 12) and *cis*-3, 6, 9, 12-octadecatetraenoic acid (C18: 4Δ-6, 9, 12, 15), which are the Δ-6 desaturation products of LA and ALA, respectively. These prospects were positively supported by definitive assignments of the compounds in peaks 6 and 8 by GC-MS analyses (data not shown). In a separate experiment, when DGLA (C20:3Δ-8, 11, 14), a substrate of Δ-5 desaturase, was added to our expression system, no extra peak was observed in chromatograms from the r24a/r24b recombinants, compared to the negative control. Taken together, the recombinant yeast containing the inducible r24 cDNA had gained function of Δ-6, but not Δ-5, fatty acid desaturation.

DISCUSSION

Here we isolated a rat liver cDNA coding for the Δ-6 fatty acid desaturase. Although the cDNA, r24, was successfully expressed in yeast, we could not predict the actual ATG initiation codon corresponding to a methionine residue at the amino terminus of the native desaturase protein. This is because, in our study, no significant differences have not been detected between the two lines of expression analyses on r24a and r24b. This observation suggested no other than the needless of the first 17 amino acids in the protein expressed from r24a to function in yeast although this portion might be indispensable in rat. Another set of experiments including the purification of the native Δ-6 desaturase is essential to clarify this point and is being undertaken.

Okayasu, *et al.* (17) described a purification of rat liver linoleoyl-CoA desaturase that was capable of converting linoleoyl-CoA to γ-linolenoyl-CoA *in vitro*. The apparent molecular weight of this enzyme (66 kD) obviously differs from either molecular weights calculated from the deduced amino acid sequence of r24a (52.4 kD) or r24b (50.7 kD). This inevitably raises a possibility of the presence of more than two types of the enzymes taking charge of the Δ-6 fatty acid desaturation. Sprecher and his colleagues have proposed a novel pathway, docosapentaenoic acid to docosahexaenoic acid via Δ-6 desaturation, for the biosynthesis of polyunsaturated fatty acids (20, 21). However, the putative involvement of a single cycle of peroxisomal β-oxidation in this pathway is under a critical reevaluation, excluding also the necessity of the proposed Δ-6 desaturation step (22). A metabolic study by Christiansen, *et al.* (23) suggested that liver microsomes might contain separate enzymes for desaturation of LA and ALA. Their observations, however, seem to be inconsistent with a result of competitive study using fatty acid tracers (24), implying that a single enzyme may govern desaturating fatty acids at Δ-6 position. To date, no clear conclusions have been made whether multiple forms of Δ-6 desaturase exist.

In relation to these pending questions, we are attempting to isolate and characterize a full-length cDNA corresponding to the EST clones W53753, AA512429, and AA036321 since nucleotide sequences of these clones can be translated into amino acid sequences that are significantly homologous, but not

identical, to the sequence from our clone r24 (data not shown). This gene may encode an isoform of the Δ-6 desaturase, which is dominantly expressed in tissues other than liver or at the different developmental stages. This assumption does not contradict the facts that we were unable to isolate a liver cDNA whose sequence is matched with the probe m3 (from W53753), and these ESTs are derived from embryo and mammary gland. Otherwise, a protein encoded by this gene may be one of other desaturases, for example, Δ-5 desaturase which has not yet been identified in mammals. In either case, the cloning of the mammalian desaturase gene(s) will accelerate to elucidate the molecular mechanisms on the regulation of various cellular events by the enzyme possibly through the alteration of physical state of membrane lipids and of the level of pooled precursors for signal transducers.

ACKNOWLEDGMENTS

We thank Dr. Dai Hirata for his helpful advice on management of yeast. This work was supported in part by a Grant-in-Aid for Encouragement of Young Scientists (#10760052) from the Ministry of Education, Science and Culture, Japan.

Cloning, Expression, and Nutritional Regulation of the Mammalian Δ-6 Desaturase*

(Received for publication, September 21, 1998)

Hyekyung P. Cho, Manabu T. Nakamura, and Steven D. Clarke‡

From the Program of Nutritional Sciences and the Institute for Cellular and Molecular Biology, The University of Texas-Austin, Austin, Texas 78712

Arachidonic acid (20:4(n-6)) and docosahexaenoic acid (22:6(n-3)) have a variety of physiological functions that include being the major component of membrane phospholipid in brain and retina, substrates for eicosanoid production, and regulators of nuclear transcription factors. The rate-limiting step in the production of 20:4(n-6) and 22:6(n-3) is the desaturation of 18:2(n-6) and 18:3(n-3) by Δ-6 desaturase. In this report, we describe the cloning, characterization, and expression of a mammalian Δ-6 desaturase. The open reading frames for mouse and human Δ-6 desaturase each encode a 444-amino acid peptide, and the two peptides share an 87% amino acid homology. The amino acid sequence predicts that the peptide contains two membrane-spanning domains as well as a cytochrome b_5-like domain that is characteristic of nonmammalian Δ-6 desaturases. Expression of the open reading frame in rat hepatocytes and Chinese hamster ovary cells instilled in these cells the ability to convert 18:2(n-6) and 18:3(n-3) to their respective products, 18:3(n-6) and 18:4(n-3). When mice were fed a diet containing 10% fat, hepatic enzymatic activity and mRNA abundance for hepatic Δ-6 desaturase in mice fed corn oil were 70 and 50% lower than in mice fed triolein. Finally, Northern analysis revealed that the brain contained an amount of Δ-6 desaturase mRNA that was several times greater than that found in other tissues including the liver, lung, heart, and skeletal muscle. The RNA abundance data indicate that prior conclusions regarding the low level of Δ-6 desaturase expression in nonhepatic tissues may need to be reevaluated.

Long chain polyunsaturated fatty acids such as 20:4(*n*-6) and 22:6(*n*-3) play pivotal roles in a number of biological functions including brain development, cognition, inflammatory responses, and hemostasis (1–4). Over 30% of the fatty acid in brain phospholipid consists of 20:4(*n*-6) and 22:6(*n*-3), and approximately 50% of the fatty acid in the retina is 22:6(*n*-3) (5, 6). An inadequate availability of 20:4(*n*-6) is associated with impaired nerve transmission, reduced eicosanoid synthesis, and impaired fetal growth (7–9). Recently, premature infants were found to have reduced cognitive development, apparently because they could not synthesize adequate quantities of 22:6(*n*-3) to meet the biological demands for proper retina function (1, 10). In addition to being vital components of membrane phospholipids and functioning in key steps of cell signaling, 20- and 22-carbon polyunsaturated fatty acids govern the expression of a wide array of genes, including those encoding proteins involved with lipid metabolism, thermogenesis, and cell differentiation (11–14).

The availability of 20- and 22-carbon (*n*-6) and (*n*-3) polyenoic fatty acids is greatly dependent upon the rate of desaturation of 18:2(*n*-6) and 18:3(*n*-3) by Δ-6 desaturase (15). Δ-6 Desaturase is a microsomal enzyme (15) and is thought to be a component of a three-enzyme system that includes NADH-cytochrome b_5 reductase, cytochrome b_5, and Δ-6 desaturase (16). The enzymatic activity for Δ-6 desaturase is reportedly low in most tissues except the liver (16). Consequently, the liver has been considered the primary site for the production of long chain polyenoic fatty acids (17, 18). Numerous dietary studies indicate that hepatic Δ-6 desaturase activity is induced by diets low in essential fatty acids and suppressed by diets rich in vegetable or marine oils (19, 20). In addition, Δ-6 desaturase activity is induced by peroxisome proliferators and by the administration of insulin to diabetic rats (21, 22). Unfortunately, defining the molecular determinants of Δ-6 desaturase activity, as well as characterizing its developmental pattern and tissue distribution, has been hampered by the fact that Δ-6 desaturase has been neither cloned nor reproducibly purified. Therefore, our objective was to clone the mammalian Δ-6 desaturase and utilize the cDNA to examine the tissue distribution and nutritional regulation of Δ-6 desaturase mRNA.

EXPERIMENTAL PROCEDURES

Cloning of the Mouse Δ-6 Desaturase cDNA—A murine cDNA (GenBank accession number W53753) displaying high homology to the amino acid sequence of Δ-6 desaturase from *Synechocystis* sp. was acquired and sequenced. Subsequently, a 23-base oligonucleotide primer (5′-CTTGGCATCGTGGGGAAGAGGTG-3′) specific for the 5′ end of murine cDNA W53753 was synthesized and utilized to screen a mouse adaptor-ligated liver cDNA library (Marathon-Ready cDNA; CLONTECH) by rapid amplification of cDNA ends-PCR.[1] The PCR conditions consisted of an initial denaturation step of 94 °C for 1 min, followed by 5 cycles of 94 °C for 10 s and 72 °C for 4 min, 5 cycles of 94 °C for 10 s and 70 °C for 4 min, and, finally, 20 cycles of 94 °C for 10 s and 68 °C for 4 min. The resulting rapid amplification of cDNA ends-PCR product was cloned into pBluescript (Stratagene) and sequenced by the dideoxy chain termination method (23).

The nucleotide sequence of the PCR product was utilized to BLAST search the mouse EST database. Two mouse cDNAs (GenBank accession numbers AA237892 and AA250162) possessing 100% nucleotide homology with our PCR product were identified and acquired from Genome Systems. Clone AA250162 contained two possible AUG start codons, and the EST cDNA AA237892 contained an apparent stop codon. The two EST cDNAs were fused at the *Sty*I restriction site, and

[1] The abbreviations used are: PCR, polymerase chain reaction; ORF, open reading frame; EST, expressed sequence tag; CHO, Chinese hamster ovary; kb, kilobase pair(s).

the product was inserted into the cytomegalovirus promoter expression vector pcDNA3.1 (Invitrogen). Sequence analysis and prediction of amino acid sequence were performed using MacDNASIS pro (Hitachi), and a translation initiator codon was determined based on Kozak's rule (24).

Cloning of the Human Δ-6 Desaturase cDNA—Using the nucleotide sequence of mouse liver Δ-6 desaturase, the EST human database was searched for a human homologue cDNA. The search identified a highly homologous human brain EST cDNA (GenBank accession number Z44979), which was purchased from Genome Systems and sequenced for verification. The 5′ end of the human cDNA was extended by PCR using a human brain cDNA library (Marathon-Ready cDNA; CLONTECH). The forward oligonucleotide primer (5′-AGACTGGCAGCATGGGGAAG-3′) was prepared using the 5′ end of the mouse Δ-6 desaturase and designed to include the putative start codon. The reverse primer (5′-CATGGTGGGGAAGAGGTGGTG-3′) was prepared from the sequence derived from human Z44979 cDNA.

Expression of the Mouse Δ-6 Desaturase—Cellular expression of the mouse Δ-6 desaturase was performed in rat primary hepatocytes and CHO cells. Rat primary hepatocytes were isolated by collagenase perfusion and allowed to attach to a collagen-coated 60-mm culture plate in 3 ml of Waymouth 752 medium supplemented with 0.5% fetal bovine serum and 1 μM insulin and dexamethasone (25). After a 6-h attachment period, the cells were washed with phosphate-buffered saline and transfected with 6 μg of the mouse Δ-6 desaturase expression plasmid or the pcDNA3.1 expression vector alone using 6.6 μl of Lipofectin per μg of DNA (Life Technologies, Inc.). Transfection was conducted by adding the mixture of Lipofectin and DNA in the absence of fetal bovine serum. After the 12-h transfection period, the medium was replaced with the one containing either 200 μM albumin-bound 18:2, n-6 (molar ratio of fatty acid to albumin, 4:1) or albumin alone. CHO cells were grown in Kaighn's modification of Ham's F-12 medium supplemented with 10% fetal bovine serum in a 25-cm^2 flask. At 80% confluence, the serum-containing medium was removed, and cells were washed with phosphate-buffered saline for transfection. A mixture of 2 μg of the mouse Δ-6 desaturase expression plasmid, 12 μl of LipofectAMINE, and 8 μl of Plus reagent (Life Technologies, Inc.) was added to cells without serum for 4 h. Subsequently, 10% serum was added to the transfection media for 8 h. After a total 12-h transfection period, the CHO cells were treated with either 200 μM albumin-bound 18:3(n-3), 20:3(n-6), or albumin alone. The hepatocytes and CHO cells were incubated with the treatment medium for 24 h and then used for fatty acid analysis.

Fatty Acid Extraction and Analysis—Cellular fatty acid was extracted by saponifying fatty acids using 1 ml of 30% KOH and 1 ml of ethanol. Fatty acids from the treatment medium were also extracted and analyzed after 24 h of incubation. Heptadecanoic acid was added to the saponification mixture as an internal standard. After saponification, the nonsaponifiable lipids were removed by extraction with petroleum ether. Subsequently, the solution was acidified, and the fatty acids were extracted with petroleum ether. The extract was dried under nitrogen, and the residue was methylated using 14% boron trifluoride in methanol (Sigma). Methylated fatty acids were separated and quantified by gas chromatography using a fused silica glass capillary column (50 m × 530 μm internal diameter; Quadrex). The column temperature program was composed of an initial hold at 140 °C for 5 min, ramping at 5 °C per min to 220 °C, and a final hold at 220 °C for 7 min. The injector temperature was 250 °C, and the flame ionization detector temperature was 260 °C.

Nutritional Regulation of Δ-6 Desaturase Expression—Male BALB/c mice were fed a high-glucose, fat-free diet for a 7-day adaptation period. After this period, the fat-free diet was supplemented with either 10% corn oil or 10% triolein (Sigma; 99% purity), and the mice (n = 4 mice/group) were fed for an additional 5 days. Liver tissues were removed, and microsomes were isolated by differential centrifugation. One g of liver was homogenized in 4 ml of homogenization buffer containing 50 mM potassium phosphate, pH 7.4, and 0.25 M sucrose. After a 10-min centrifugation of the homogenate at 10,000 × g, the resulting supernatant was spun at 100,000 × g for 60 min to isolate a microsomal pellet. After resuspending the pellet in homogenization buffer, 3 mg of microsomal protein were incubated in a 37 °C shaking water bath for 5 min with 1 ml of reaction mixture including 1.2 mM NADH, 3.6 mM ATP, 0.5 mM coenzyme A, 4.8 mM $MgCl_2$, 72 mM phosphate buffer, pH 7.4, and 50 nmol of 1-^{14}C-labeled 18:2(n-6). The reaction was stopped by adding saponification reagent, and fatty acids were saponified and methylated as described above. Radioactive 18:2(n-6) and 18:3(n-6) were separated by silver nitrate-impregnated thin layer chromatography. The radioactivity was quantified using an Ambis radio-imager. Δ-6 Desaturase enzyme activity is expressed as the percentage of 18:2(n-6) converted to 18:3(n-6) per mg of protein/min.

RNA Extraction and Northern Blot Analysis—Total RNA was isolated from the liver of mice in the dietary study using the phenol-guanidinium isothiocyanate method (26). Twenty μg of total RNA were size-fractionated on a 1% formaldehyde gel and then transferred to a Zeta probe nylon membrane (Bio-Rad). The mouse Δ-6 desaturase probe was prepared by incorporating [^{32}P]dCTP by PCR. The forward primer was 5′-GGACATAAAGAGCCTGCATG-3′, and the reverse primer was 5′-ACTGGAAGTACATAGGGATG-3′. The Northern membrane of human tissues was purchased from Invitrogen. The radiolabeled probe for the human tissue blot was a 200-base pair PCR fragment of human Δ-6 desaturase using primers of 5′-GGCAAGAACTCAAAGATCAC-3′ and 5′-GAGAGGTAGCAAGAACAAAG-3′. The autoradiographic signal was quantified using Instant Imager (Packard).

RESULTS

Cloning Mouse and Human Δ-6 Desaturase—The mouse EST database was searched for mammalian homologues using the amino acid sequence for Δ-6 desaturase from the photosynthetic cyanobacterium *Synechocystis* sp. (27). A mouse cDNA that had a 60% similarity to a 46-amino acid sequence of *Synechocystis* Δ-6 desaturase was identified. A 1508-base pair cDNA sequence for mouse liver Δ-6 desaturase was acquired using a combination of ligation-mediated PCR screening of a mouse liver cDNA library and BLAST searches of the mouse EST database (Fig. 1*A*). Sequence analysis revealed the presence of two in-frame methionine codons located at positions 75 and 126. In addition, a TGA termination sequence was identified at position 1407. Kozak's rule, which predicts that the favored eukaryotic translation initiation sequence resides in the sequence of AXXATGG (24), indicated that the first of the two ATG codons was the preferred initiation codon for the putative Δ-6 desaturase. The apparent ORF between the first ATG codon and the TGA termination codon predicted a peptide consisting of 444 amino acids and having a size of 52.2 kDa. The human brain cDNA homologue for Δ-6 desaturase contains an initiation codon and a termination codon that are perfectly aligned with the initiation and termination codons of the mouse cDNA (Fig. 1*A*). Moreover, the amino acid sequence derived from the ORF revealed that 87% of the amino acid sequence for the mouse and human homologues was identical, and 96% of the sequence had similarity (Fig. 1*B*). A search of the Swiss Protein Database indicated that the putative Δ-6 desaturase sequence was unique and shared very little amino acid homology with any other mammalian proteins including the murine stearoyl-CoA desaturase (Δ-9 desaturase) (28).

Structural Characteristics of Mammalian Δ-6 Desaturase—The enzymatic activity of mammalian Δ-6 desaturase is associated with the microsomal membrane fraction (15). Consistent with such membrane involvement, the predicted amino acid sequence for Δ-6 desaturase indicated that the peptide contains 52% nonpolar amino acids, and a hydropathy profile revealed the presence of two membrane-spanning domains that are characteristic of membrane-anchored proteins (Figs. 1*B* and 2). In addition, the amino terminus of the Δ-6 desaturase peptide contains a hydrophilic domain of 54 amino acids that is highly homologous with the heme-binding domain of cytochrome b_5 (Fig. 3*A*). This cytochrome b_5-like domain is also found in the Δ-6 desaturases from *Borago officinalis* (29) and *Caenorhabditis elegans* (30) (Fig. 3*A*). The His^{53} and His^{75} residues located within this domain of the mammalian Δ-6 desaturase are exactly aligned with the two heme-binding histidines in cytochrome b_5 (31). Moreover, these two histidines are surrounded by charged amino acids that may contribute to the stabilization of the heme-histidine complex (31). In addition, the sequence ^{53}HPGG^{56} predicts the existence of a dramatic β-turn that may render His^{53} more accessible to heme iron binding (31).

A second noteworthy feature of the mammalian Δ-6 desaturase is the presence of three histidine-rich regions (Fig. 3*B*

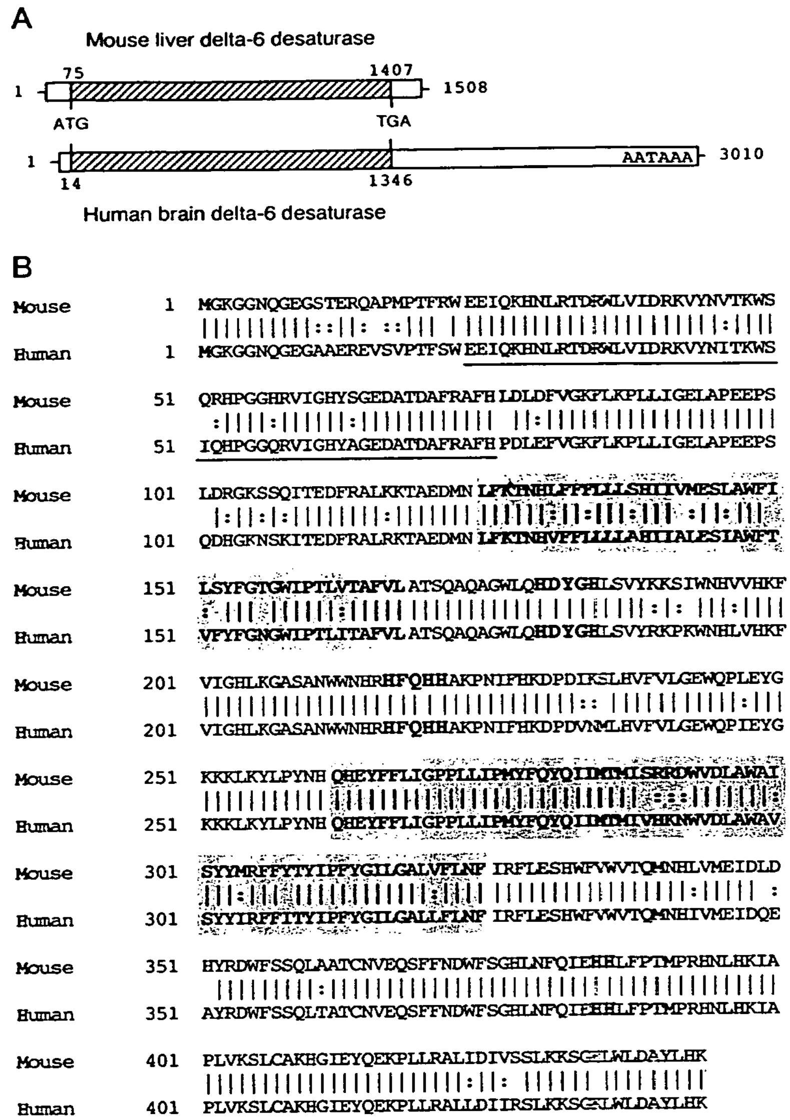

FIG. 1. **Alignment of the predicted amino acid sequences for mouse and human Δ-6 desaturase.** *A*, schematic diagram of the ORF and untranslated regions for mouse and human Δ-6 desaturase. The *hatched box* indicates an ORF of 1332 nucleotides, and the *open boxes* represent untranslated regions. The human cDNA contains a polyadenylation signal AATAAA at the 3′ end. *B*, a comparison of the amino acid sequences for mouse and human Δ-6 desaturase predicted by the nucleotide sequence of the ORFs. Both mouse and human ORFs encode 444 amino acids. Identical amino acids are paired by *vertical lines*, and conserved amino acids are matched by *colons*. The cytochrome b_5-like domain is *underlined*. Transmembrane domains are shown in *shaded areas*, and three histidine-rich domains are in *bold*.

Regions I (HX_3H) and II (HX_2HH) are located between the two transmembrane domains, and region III (HH) is located near the carboxyl terminus of the peptide. These histidine-rich regions are also found in plant membrane desaturases and mammalian stearoyl-CoA desaturase and reportedly bind non-heme iron that is required for enzymatic activity (32).

Expression of Δ-6 Desaturase—The predicted structural characteristics of the mouse and human peptides strongly suggested that the cDNAs did in fact correspond to mammalian Δ-6 desaturase. To confirm this conclusion, the ORF for the mouse Δ-6 desaturase was expressed in primary cultures of rat hepatocytes and in CHO cells. Fatty acid analysis revealed that hepatocytes transfected with the vector containing the Δ-6 desaturase ORF were capable of synthesizing the Δ-6 desaturase product 18:3(n-6) from 18:2(n-6) (Fig. 4*A*). On the other hand, hepatocytes transfected with vector alone produced no detectable 18:3(n-6) product (Fig. 4*B*). Similarly, CHO cells expressing Δ-6 desaturase readily converted the Δ-6 desaturase substrate 18:3(n-3) to the Δ-6 desaturase product 18:4(n-3), whereas nontransfected CHO cells were unable to produce detectable levels of 18:4(n-3) (Fig. 4, *C* and *D*). In contrast, providing CHO cells with the Δ-5 desaturase substrate 20:3(n-6) did not lead to the production of the Δ-5 desaturase product 20:4(n-6) (data not shown). These data conclusively demonstrate that the mouse and human ORFs do in fact encode mammalian Δ-6 desaturase.

Nutritional Regulation of Δ-6 Desaturase Expression—The enzymatic activity of Δ-6 desaturase increases when animals are fed an essential fatty acid-deficient diet, whereas it decreases when polyunsaturated fatty acids are ingested (16, 19, 20). Using the mouse cDNA for Δ-6 desaturase, we have found that the suppression of hepatic Δ-6 desaturase enzymatic activity associated with the ingestion of polyunsaturated fat (*i.e.* corn oil) is paralleled by a comparable reduction in Δ-6 desaturase mRNA abundance (Fig. 5, *A* and *B*). Interestingly, whereas the dominant transcript of hepatic Δ-6 desaturase is approximately 4.0 kb in size, the mouse liver also contains a minor transcript that is approximately 2.2 kb (Fig. 5*B*). Both transcripts appeared to be suppressed by dietary corn oil to the same degree. In addition, hybridizing the Northern blot with sequences from the 5′, middle, and 3′ regions of the Δ-6 desaturase ORF yielded the same outcomes with respect to the abundance and dietary response of the 2.2-kb transcript (data not shown). The reason for these two different transcripts remains unknown.

Δ-6 Desaturase mRNA Distribution in Human Tissues—

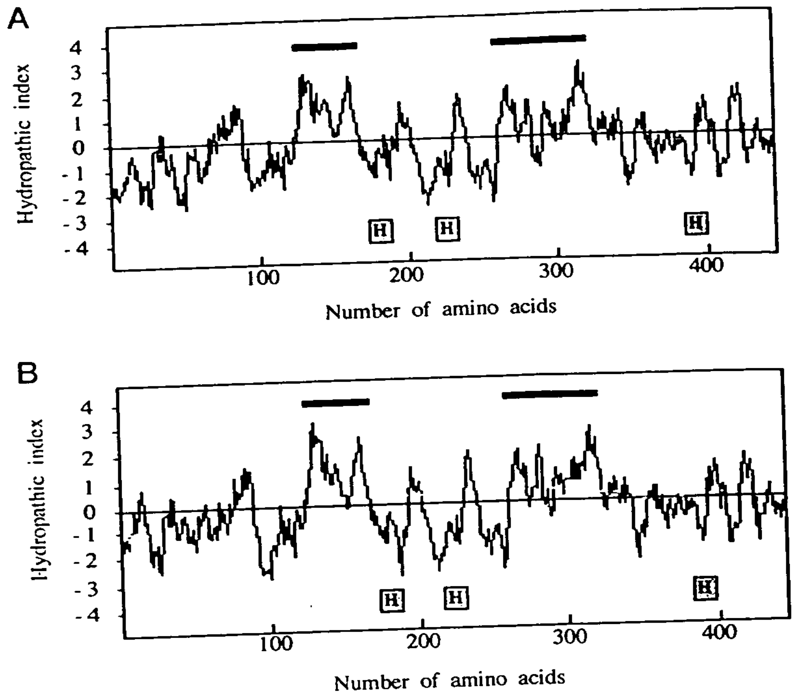

FIG. 2. **Hydropathy profile of mouse (*A*) and human (*B*) Δ-6 desaturase.** The hydropathic pattern for Δ-6 desaturase was plotted using the method of Kyte-Doolittle, and the amino acid sequences were predicted by the respective ORFs. *Bars*, the transmembrane regions. *Boxed H*, locations of histidine-rich regions.

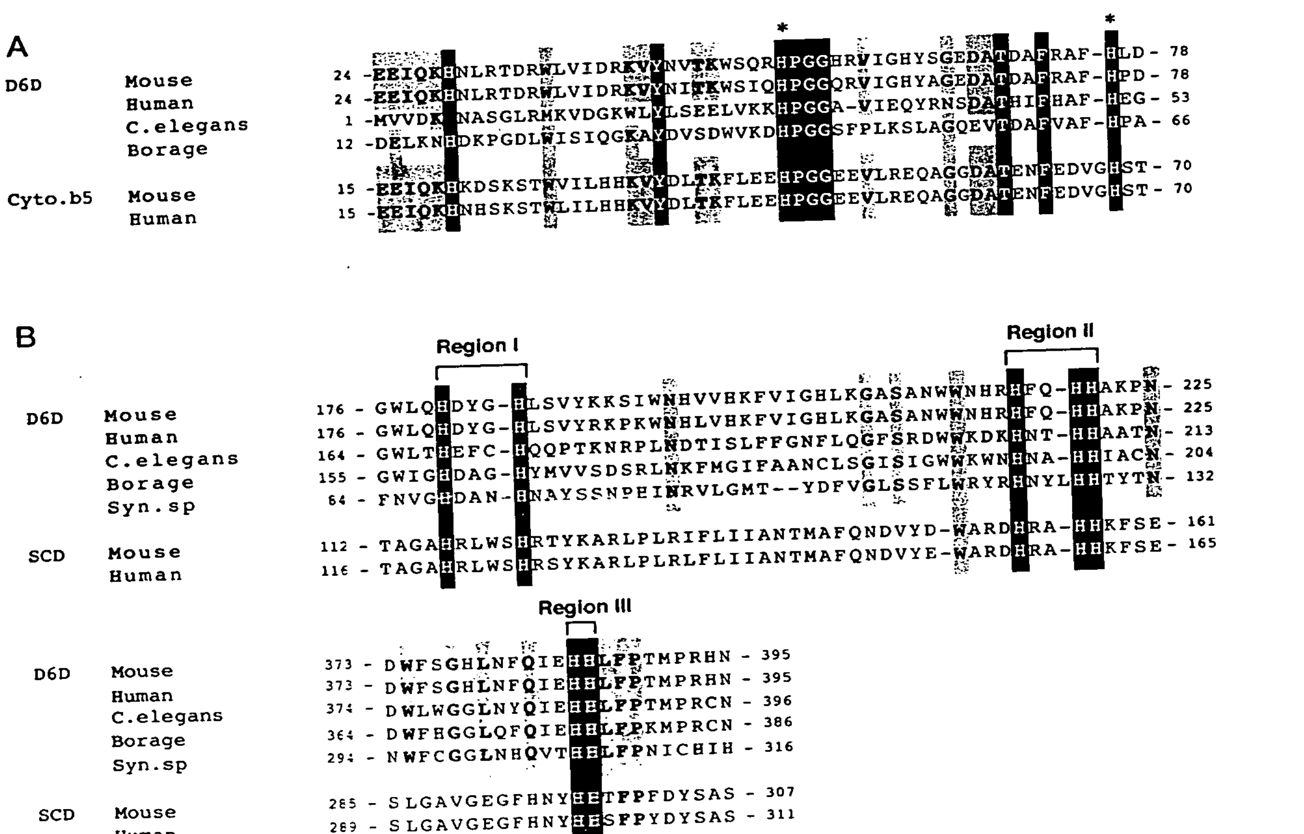

FIG. 3. **A comparison of the cytochrome b_5-like and histidine-rich domains for mammalian and nonmammalian Δ-6 desaturases.** *A*, a comparison of the cytochrome b_5-like domain for mammalian and nonmammalian Δ-6 desaturase (*D6D*). A comparison of the amino acid sequence within the cytochrome b_5-like domain of mouse, human, plant (*B. officinalis*; Ref. 29), and *C. elegans* (30) Δ-6 desaturases reveals a high level of homology with a comparable domain within mammalian cytochrome b_5 (*Cyto.b5*) (31). Amino acids that are identical between the Δ-6 desaturases and cytochrome b_5 are highlighted in *black*; amino acids that are highly homologous between the desaturases and cytochrome b_5 are highlighted in *gray*. *Asterisk*, two heme-binding histidines found in cytochrome b_5 (31). *B*, the three histidine-rich regions conserved in membrane desaturases. The histidines within these regions are highlighted in *black*. The amino acids that are identical in all the Δ-6 desaturases listed are highlighted in *dark gray*.

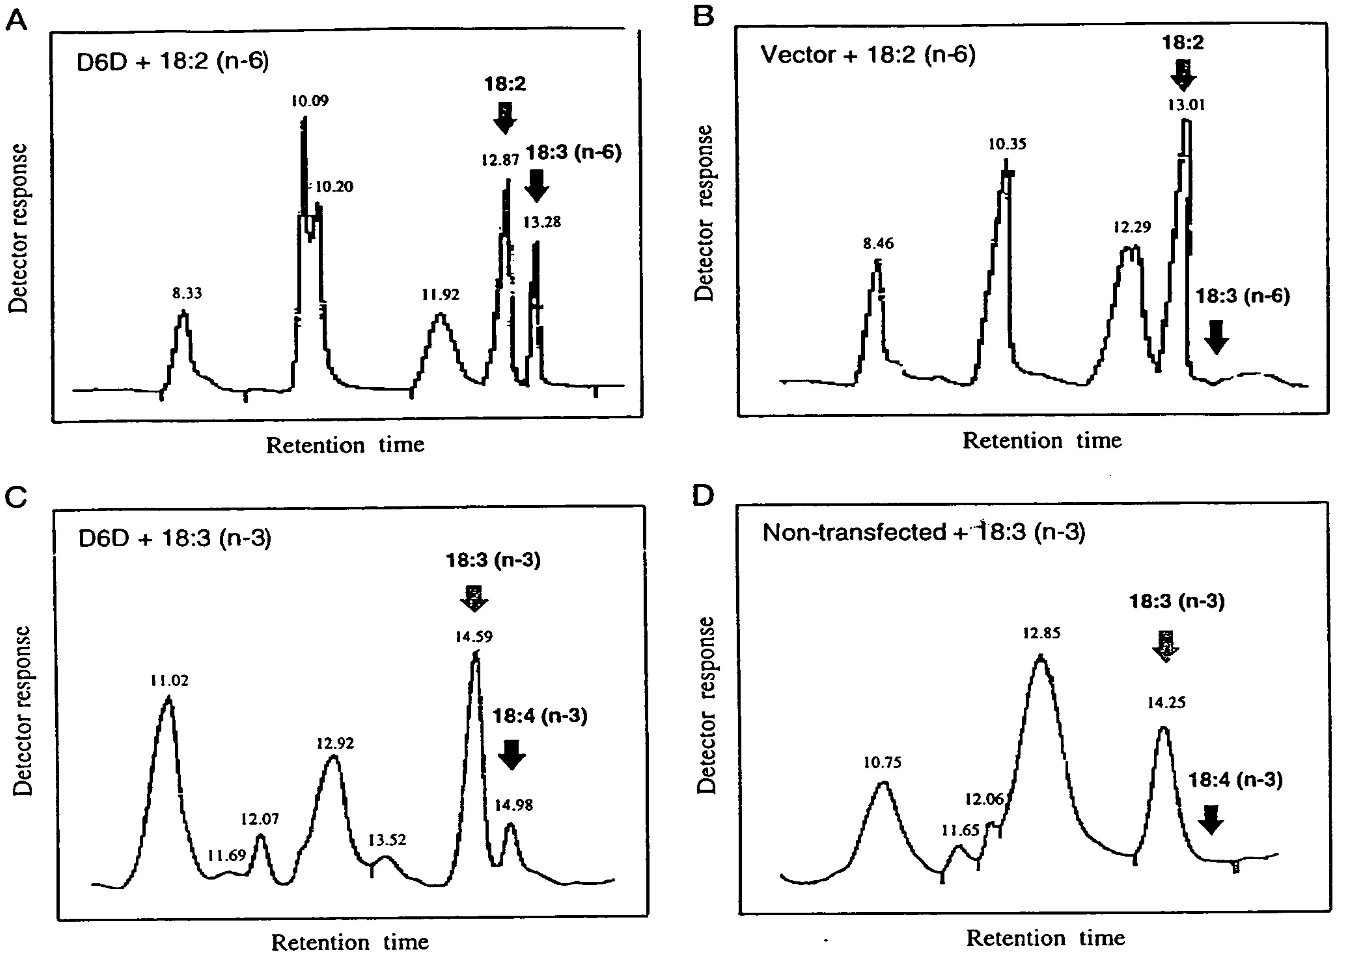

FIG. 4. **Expression of mouse Δ-6 desaturase in rat hepatocytes and CHO cells.** *A* shows the conversion of 18:2(n-6) to 18:3(n-6) by hepatocytes that were transfected with the pcDNA3.1 vector containing the mouse Δ-6 desaturase (*D6D*) ORF. When hepatocytes were transfected with pcDNA3.1 vector lacking the Δ-6 desaturase ORF, there was no detectable conversion of 18:2(n-6) to 18:3(n-6) (*B*). The media of CHO cells incubated with albumin-bound 18:3(n-3) and transfected with the Δ-6 desaturase expression vector pcDNA3.1 contained 18:4(n-3) (*C*), whereas the media of nontransfected CHO cells contained no detectable 18:4(n-3) (*D*). Retention times for the fatty acids are shown *above* the respective peaks. The identity of each peak was confirmed using individual fatty acid methyl ester standards.

Northern analysis of Δ-6 desaturase expression revealed that human Δ-6 desaturase mRNA is a single transcript of approximately 3.2 kb and is expressed in a wide array of tissues including the brain, liver, lung, and heart (Fig. 5*C*). The level of Δ-6 desaturase mRNA in the liver was approximately the same as that found in the lung and heart, but the abundance of Δ-6 desaturase in the human brain was severalfold higher (Fig. 5*C*). In addition to the tissues examined by Northern analysis, a search of the EST database revealed that Δ-6 desaturase mRNA is expressed in the human fetus and fetal heart as well as in the 13-day-old mouse embryo heart.

DISCUSSION

The purification and characterization of mammalian Δ-6 desaturase have been difficult because of its instability. In fact, there has been only one report, in 1981, that describes the purification of a putative linoleoyl-CoA desaturase from rat liver (33). Because of the problems encountered in the purification of Δ-6 desaturase, we have used the EST database to clone and characterize the mouse and human Δ-6 desaturase enzyme. Interestingly, a comparison of the rat liver linoleoyl-CoA desaturase with the Δ-6 desaturase peptide predicted by the ORF of both the mouse and human cDNAs indicates that the two proteins are markedly different. First, the ORF for mouse and human Δ-6 desaturase predicts a protein that is 52.2 kDa, whereas the size of the linoleoyl-CoA desaturase was cited to be 66 kDa (33). Second, the nucleotide sequence of the mouse and human Δ-6 desaturase ORFs predicts that these peptides contain 30 histidines (Fig. 1*B*). Moreover, many of these histidines are organized into distinct histidine-rich domains. Such domains are characteristic of all membrane-associated desaturases (32). In contrast, the reported amino acid composition of linoleoyl-CoA desaturase indicates that it contains only 15 histidine residues (33). Unfortunately, sequence information for linoleoyl-CoA desaturase is not available, because the purification of linoleoyl-CoA desaturase has never been replicated since the initial report. Clearly, the Δ-6 desaturase and the putative linoleoyl-CoA desaturase are distinctly different proteins. It is possible the liver contains two Δ-6 desaturase enzymes. In fact, metabolic studies suggest that there may be two isoforms of Δ-6 desaturase (34, 35): (*a*) one that catalyzes the initial desaturation of 18:2(n-6) or 18:3(n-3), and (*b*) another that catalyzes the conversion of 24:5(n-3) to 24:6(n-3). The cloning of the Δ-6 desaturase should now permit us to determine whether isoforms of Δ-6 desaturase do exist.

In addition to the histidine-rich domains, the mammalian Δ-6 desaturase contains a distinct cytochrome b_5-like domain

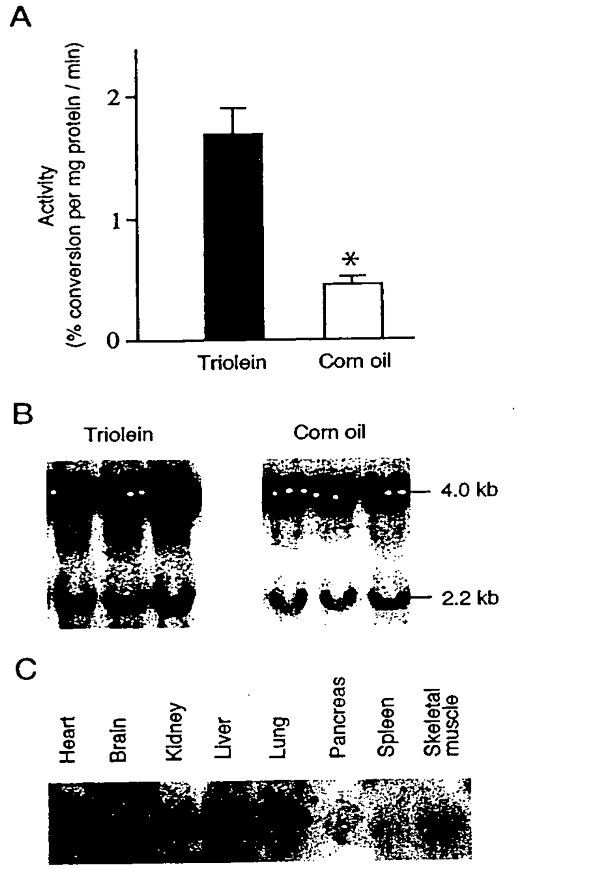

FIG. 5. **Nutritional regulation and tissue distribution of mammalian Δ-6 desaturase.** Mice were fed a high-glucose diet containing 10% corn oil or 10% triolein. Hepatic Δ-6 desaturase activity, which is expressed in *A* as means ± S.E., was significantly lower in mice fed corn oil than in mice fed triolein ($p < 0.001$). The abundance of hepatic Δ-6 desaturase mRNA was determined by Northern analysis (*B*). The abundance of the 4.0- and 2.2-kb Δ-6 desaturase transcripts was quantified by radio-imaging. The cpm of the ^{32}P-labeled probe associated with the 4.0- and 2.2-kb transcripts was 2509 ± 154 and 327 ± 17; it was 1264 ± 66 and 185 ± 9 for the triolein and corn oil groups, respectively ($p <$ [illegible]3). *C* depicts the abundance of Δ-6 desaturase mRNA found in a [illegible]ty of adult male human tissues. Each lane contains 20 μg of total RNA. Unlike mice, only one Δ-6 desaturase transcript with an approximate size of 3.2 kb was detected in human tissues. Comparable results were obtained with three different Northern blots.

that is also characteristic of plant (*Borage*) and *C. elegans* Δ-6 desaturases (29, 30) but is not a component of the mammalian Δ-9 desaturase (36). Early reconstitution studies with Δ-9 desaturase indicated that the conversion of 18:0(*n*-9) to 18:1(*n*-9) required Δ-9 desaturase, cytochrome b_5 reductase, and cytochrome b_5 itself (36). It has been assumed from these early studies that all mammalian desaturases require cytochrome b_5 for enzymatic activity (16, 36). However, the cytochrome b_5-like domain of yeast OLE1 was recently reported to replace the requirement for cytochrome b_5; *i.e.* desaturation occurred in the absence of cytochrome b_5, and removal of the cytochrome b_5-like domain rendered the OLE1 enzyme inactive (37). This observation raises the possibility that cytochrome b_5 reductase transfers electrons to the catalytic domain of the Δ-6 desaturase via the cytochrome b_5-like domain, and not via cytochrome b_5 per se.

Hepatic Δ-6 desaturase enzymatic activity varies with hormonal and nutritional manipulation (15, 16, 20, 38). For example, insulin deficiency and fasting reduce Δ-6 desaturase enzymatic activity, whereas the administration of insulin or refeeding increases its activity (39). In addition to being affected by fasting and feeding, hepatic Δ-6 desaturase enzymatic activity is highly dependent upon the composition of dietary fat (16). Specifically, the ingestion of fats that are low in essential fatty acids (*e.g.* butter) results in higher levels of enzyme activity than the consumption of fats (*e.g.* corn oil) that are rich in essential fatty acids (16). Northern analysis indicates that the increase in hepatic Δ-6 desaturase activity associated with the consumption of an essential fatty acid-deficient diet is paralleled by a comparable increase in the hepatic abundance of Δ-6 desaturase mRNA (Fig. 5). Thus, it appears that the activity of hepatic Δ-6 desaturase is largely regulated by pretranslational events. However, this may not be the case in all tissues. Specifically, Δ-6 desaturase activity is reportedly very low in nonhepatic tissues (16–18). Because of this low enzymatic activity in nonhepatic tissues, the liver has been considered to be the primary site of 20:4(*n*-6), 20:5(*n*-3), and 22:6(*n*-3) production for peripheral tissue utilization (17). However, Northern analysis of RNA from a number of different human tissues challenges this concept (Fig. 5*C*). For example, the level of Δ-6 desaturase mRNA in the human liver was comparable to that found in the human lung and heart. Moreover, the abundance of Δ-6 desaturase mRNA in the adult human brain was severalfold greater than that in the human liver (Fig. 5*C*). This high level of expression is certainly very consistent with the fact that >30% of the human brain phospholipid consists of 20- and 22-carbon polyenoic fatty acids (5, 6, 40). However, such high expression is in conflict with the reports that brain microsomes have a rate of Δ-6 desaturation that is only 10–15% of that found in the liver (18, 41). These data suggest that Δ-6 desaturase enzymatic activity may be determined by tissue-specific mechanisms that involve both pre- and post-translational events.

In conclusion, Δ-6 desaturase catalyzes the rate-limiting step in the conversion of 18:2(*n*-6) and 18:3(*n*-3) to the long chain polyenoic fatty acids 20:4(*n*-6) and 20:5(*n*-3) and 22:6(*n*-3), respectively (15). These long chain polyenoic fatty acids are essential for a large number of biological functions including inflammatory responses (4), brain development (2), retina function and cognition (1, 3), signal transduction (42, 43), reproduction (4), fetal growth (9), cell differentiation (14), and gene regulation (11–13). Not surprisingly, physiological conditions that are associated with low levels of Δ-6 desaturase activity may have a pronounced impact on a wide array of biological functions. For example, an impaired conversion of 18:2(*n*-6) to 18:3(*n*-6) appears to be associated with reduced nerve conductivity in human diabetics (7). Similarly, the low rate of 18:3(*n*-3) conversion to 20:5(*n*-3) and 22:6(*n*-3) observed in newborn infants is highly correlated with impaired retina function and reduced cognitive development (1). Now that the Δ-6 desaturase has been cloned, we can begin to define the role that Δ-6 desaturation may play in an apparently wide array of physiological processes.

Communicated by Jake MacMillan, University of Bristol, United Kingdom, January 23, 1997 (received for review November 28, 1996)

ABSTRACT **γ-Linolenic acid (GLA; C18:3 $\Delta^{6,9,12}$) is a component of the seed oils of evening primrose (*Oenothera* spp.), borage (*Borago officinalis* L.), and some other plants. It is widely used as a dietary supplement and for treatment of various medical conditions. GLA is synthesized by a Δ^6-fatty acid desaturase using linoleic acid (C18:2 $\Delta^{9,12}$) as a substrate. To enable the production of GLA in conventional oilseeds, we have isolated a cDNA encoding the Δ^6-fatty acid desaturase from developing seeds of borage and confirmed its function by expression in transgenic tobacco plants. Analysis of leaf lipids from a transformed plant demonstrated the accumulation of GLA and octadecatetraenoic acid (C18:4 $\Delta^{6,9,12,15}$) to levels of 13.2% and 9.6% of the total fatty acids, respectively. The borage Δ^6-fatty acid desaturase differs from other desaturase enzymes, characterized from higher plants previously, by the presence of an N-terminal domain related to cytochrome b_5.**

Δ^6-Desaturated fatty acids are of major importance in animal cells as they have roles in the maintenance of membrane structure and function, in the regulation of cholesterol synthesis and transport, in the prevention of water loss from the skin, and as precursors of eicosanoids, including prostaglandins and leucotrienes (1). In animals, members of this class of fatty acids are synthesized from the essential fatty acid linoleic acid (C18:2 $\Delta^{9,12}$), the first step being the desaturation to γ-linolenic acid (GLA; C18:3 $\Delta^{6,9,12}$) catalyzed by a Δ^6-desaturase (1). Decreased activity of this key enzyme, observed for example in aging, stress, diabetes, eczema, and some infections, or increased catabolism of GLA resulting from oxidation or more rapid cell division (e.g., in cancer or inflammation) may lead to a deficiency of GLA (reviewed in ref. 2). Clinical trials have shown that dietary supplementation with GLA may be effective in treating a number of such conditions (e.g., atopic eczema, mastalgia, diabetic neuropathy, viral infections, and some types of cancer; ref. 2). Oils containing GLA are therefore widely used as a general health supplement and have been registered for pharmaceutical use.

In the plant kingdom, GLA is an uncommon fatty acid (3). Only a small number of higher plant species synthesize GLA, and in many of these, the fatty acid is found exclusively in the seed. GLA is also present in some fungi (e.g., *Mucor javanicus*) and cyanobacteria (3). Major commercial sources of GLA (4) are evening primrose (*Oenothera* spp.), in which GLA accounts for about 8–10% of the seed oil and borage (starflower) (*Borago officinalis* L.) seeds that contain some 20–25% GLA. These plants, however, suffer from poor agronomic performance and low yield; borage, for example, produces 300–600 kg/ha in the United Kingdom (4) compared with about 3 t/ha for oilseed rape. There is therefore considerable interest in both increasing the GLA content of existing crops and the production of GLA in a conventional oil crop (such as high linoleate rape).

In the higher plant cell, the synthesis of saturated fatty acids with chain lengths up to C18 and monounsaturated fatty acids (generally with a double bond at the Δ^9 position) occurs in the plastid. Further desaturation can then occur either in the plastid or on the endoplasmic reticulum (ER; ref. 5). The desaturase enzymes of the plastid require reduced ferredoxin as an electron donor and are either soluble enzymes acting on saturated acyl-ACP substrates or membrane-bound enzymes using unsaturated fatty acids esterified to complex lipids such as monogalactosyldialglycerol. In contrast, the ER-located Δ^{12}- and Δ^{15}-desaturases use fatty acids located at the *sn*-2 position of phosphatidylcholine as substrates, and cytochrome b_5 as a cofactor (5, 6). The Δ^6-fatty acid desaturase in the developing cotyledons of borage is similar to the Δ^{12}- and Δ^{15}-desaturases in its location and substrate specificity (oleate/linoleate at the *sn*-2 position of phosphatidylcholine), and is assumed to use cytochrome b_5 as its electron donor (7, 8). In addition, α-linolenic acid esterified to phosphatidylcholine may act as a substrate, resulting in the accumulation of octadecatetraenoic acid (OTA; C18:4 $\Delta^{6,9,12,15}$) in borage leaves (9).

We describe the isolation of a cDNA clone encoding the Δ^6-fatty acid desaturase from developing seeds of borage, using a PCR-based strategy. The identity of the cDNA has been confirmed by functional expression and analysis in transgenic tobacco plants. The encoded protein differs from other membrane-bound fatty acid desaturases of plants, such as those encoded by the FAD genes of *Arabidopsis* (10, 11), in that the desaturase domain is preceded at the N terminus by a sequence that is related to cytochrome b_5 (12), the haemprotein involved in electron transport to other ER-located fatty acid desaturases ($\Delta^{12,15}$) from higher plants (8, 13).

MATERIALS AND METHODS

Nucleic Acid Manipulations. Total RNA was isolated from developing seeds of borage (*B. officinalis*) using guanidinium thiocyanate according to the method described in ref. 14. Poly(A)$^+$ RNA was purified from total RNA using oligo(dT) cellulose according to standard methods (15) and was used as

a template for cDNA library construction. Single-stranded cDNA was synthesized from total RNA using the Reverse Transcription System (Promega) according to the supplier's instructions and used as a template for PCR amplification with degenerate primers. All nucleotide sequences were determined by the dideoxy chain termination method (15), and aligned using the GCG 8 program (16).

PCR-Based Cloning. Two highly degenerate primers were synthesized for cDNA screening: forward primer A, 5′-GCGAATTC(A/G)TXGGXCA(T/C)GA(T/C)TG(T/C)G-GXCA-3′ (fully degenerate to the conserved amino acid sequence GHDCGH), and reverse primer B, 5′-GCGAATT-CATXT(G/T)XGG(A/G)AAXA(G/A)(A/G)TG(A/G)-TG-3′ (fully degenerate to conserved amino acid sequence HHLFP), where X substitutes nucleotides AGTC. Each primer contained an *Eco*RI site (underlined) at the 5′ end to facilitate subsequent manipulations. These primers were used for PCR amplification with cDNA transcribed from total RNA. Reactions were run on a Perkin–Elmer Cetus DNA thermal cycler using a program of 1 min at 94°C, 1 min at 45°C, and 2 min at 72°C for 35 cycles followed by extension for 10 min at 72°C. PCR amplification products were separated on 1.0–2% agarose gels. PCR fragments of the expected length (600–700 bp) were purified using the Wizard DNA purification system (Promega), ligated into pGEM-T Vector according to the pGEM-T Vector Cloning Kit (Promega), and transformed into XL1-blue *Escherichia coli* cells. Plasmid DNA was purified and sequenced using the Promega miniprep system.

Library Screening. Poly(A)$^+$ mRNA from developing seeds of borage was used as the template for the synthesis of a cDNA library; custom synthesis and packaging being carried out by CLONTECH. The cDNA was inserted into the *Eco*RI site of the phage vector λ ZAPII, and the resultant DNA was packaged into phage particles. The cDNA bank contained 2.0×10^6 clones with an average insert size of 2.0 kb. Filter replicas of this library were hybridized with the labeled DNA probe pBdes1 and with a tobacco cDNA encoding cytochrome b_5 (17). Radiolabeling of DNA and screening of phage libraries were conducted using standard techniques (15). The full-length cDNA clone pBdes6 was isolated and sequenced on both strands.

Northern Blot Analysis. RNA was separated by electrophoresis through 1% formaldehyde agarose gel, transferred to nylon membrane (Hybond N, Amersham), and bound by exposure to UV light for 2 min. Probes were made from the cDNA clone pBdes6 by random priming (15). The filters were hybridized and washed as described in ref. 17 and then exposed to x-ray film at −80°C using an intensifying screen.

Plant Transformation. To facilitate preparation of plant expression constructs, flanking *Sal*I and *Sma*I restriction enzyme sites were added to the coding region of clone pBdes6 by PCR amplification. Two oligonucleotides were synthesized based on the pBdes6 coding sequence: primer C, 5′-GCGTCGAC**ATG**GCTGCTCAAATCAAG-3′ (annealing to the initiating methionine, indicated in boldface type), and primer D, 5′-GCCCGGG**TTA**ACCATGAGTGTGAAG-3′ (annealing up to the complement of the stop codon, indicated in boldface type). The *Sal*I (primer C) and *Sma*I (primer D) restriction sites are underlined. The PCR product was purified and subcloned into the vector pJD330 (18) to generate the plasmid p35Bdes6. Digestion of p35Bdes6 with *Xba*I released fragment of ≈2,200 bp containing the ORF of the borage pBdes6, together with regulatory elements consisting of the cauliflower mosaic virus 35S promoter, an Ω-translational enhancer from tobacco mosaic virus (19) and the nopaline synthase (*nos*) termination sequence. This *Xba*I fragment was gel purified and cloned into pBIN19 (20) to obtain the plasmid pNTdes6, which was transformed into *Agrobacterium tumefaciens* strain LBA4404 by electroporation. Tobacco (*Nicotiana tabacum* cv. NVS) was transformed with the plant expression plasmid according to standard procedures (21). Initial transformants were selected on 50 μg/ml kanamycin and then transferred to 100 μg/ml kanamycin. Plants were maintained in axionic culture under controlled conditions.

Fatty Acid Analysis. Lipids were extracted from leaves of transformed and control tobacco plants by homogenization in MeOH-$CHCl_3$ using a modification of the method of Bligh and Dyer (22). The resulting $CHCl_3$ phase was evaporated to dryness under nitrogen gas, and the samples were transmethylated with 1 M HCl in methanol at 80°C for 1 h. Fatty acid methyl esters (FAMes) were extracted in hexane and purified using a small column packed with Florisil. Analysis of FAMes was conducted using a Hewlett Packard 5880A Series Gas Chromatograph equipped with a 25 M × 0.32 mm RSL-500BP bonded capillary column and a flame ionization detector. Fatty acids were identified by comparison of retention times with FAMe standards (Sigma) separated on the same GC. Quantitation was carried out using peak height area integrals expressed as a total of all integrals.

GC–Mass Spectrometry (MS) Analysis. Fatty acid 4,4-Dimethyloxazoline (DMOX) derivatives were prepared for GC-MS analysis by a modification of the method of Fay and Richli (23). Lipid samples (extracted from tobacco leaves as described above) were heated at 180°C in 2-amino-2-methyl-1-propanol under N_2 for 18 h. After cooling to room temperature dichloromethane and water were added. The DMOX derivatives were recovered in the dichloromethane, passed through a column of anhydrous sodium sulfate to remove water, and dried under a stream of N_2. To remove any contaminating polar material, the samples were taken up in hexane, passed through a short Florisil column, and evaporated to dryness. The samples were then dissolved in an appropriate volume of hexane for GC-MS analysis. Fatty acid DMOX derivatives were analyzed by GC-MS on a Hewlett Packard 5890 Series II Plus gas chromatograph equipped with a 50 M × 0.25 mm BPX70™ capillary column connected directly to a Hewlett Packard 5989B MS Engine quadropole mass spectrometer operating at an ionization energy of 70 eV and emission current of 300 μA. Mass spectra were interpreted by comparison to the mass spectra of DMOX derivatives of GLA and OTA prepared from blackcurrant oil, which is known to contain both these fatty acids (24), using the interpretation rules of ref. 25.

RESULTS

PCR-Based Cloning of Membrane-Bound Desaturases. Comparisons of the deduced amino acid sequences of membrane-bound fatty acid desaturases (and related proteins) from mammals, fungi, insects, higher plants, and cyanobacteria reveal three highly conserved regions (boxes) containing histidine residues (26). Since the borage seed Δ^6-desaturase is membrane-bound (27), two highly degenerate primers were constructed based on the sequences of the first and third histidine boxes present in the membrane-bound Δ^{12}- and Δ^{15}-fatty acid desaturases of plants. These primers were used in PCRs with cDNA transcribed from total RNA of developing cotyledons of borage. PCR products of the predicted length (600–700 bp) were cloned and sequenced, allowing them to be classified into three groups: 45% showed similarity to other proteins (i.e., not fatty acid desaturases), 35% resembled Δ^{12}-desaturases, and 20% formed a separate group that showed some similarity to both Δ^{12}- and Δ^{15}-desaturases but was clearly distinct from the second group.

Sequencing of a representative clone (pBdes1) from the third group revealed an ORF of 228 aa with three putative histidine boxes. Alignment of the deduced amino acid sequence with those of known desaturases (data not shown) showed highest similarity to the Δ^{15}-desaturases, although the actual level of identity was low (less than 30%). Since borage

seed oil contains little or no α-linolenic acid, it is unlikely that high levels of transcripts for Δ^{15}-desaturases would be present in the developing seeds. It was therefore considered likely that the pBdes1 PCR product encoded part of a putative Δ^{6}-desaturase.

To isolate a full-length clone corresponding to the pBdes1 PCR product, the insert was used to probe a borage developing seed cDNA library constructed in λ ZAPII. A total of 3×10^5 plaques were screened, and 20 individual phage clones that hybridized with the pBdes1 DNA probe were identified and purified by further rounds of hybridization. Restriction enzyme digestion of 15 clones recovered from positive plaques showed the presence of single inserts that hybridized with the probe, ranging from 700 to 1,800 bp in length. One of these, termed pBdes6, containing an insert of 1,800 bp, was chosen for detailed analysis.

pBdes6 encodes a 1,344-bp ORF, preceded by a 41-bp 5′ untranslated region. The coding region was followed by a stop codon and a 345-bp untranslated region with a poly(A) tail. The ORF encoded 448 aa, corresponding to a putative protein with an M_r of about 50,000, which is significantly larger than the predicted M_r of other microsomal desaturases such as the [illegible] and Δ^{15}-desaturases from *Arabidopsis* (refs. 10 and 11; Fig. 1). A degree of similarity to other fatty acid desaturases is clear, but only over a part of the coding sequence. The amino acid sequence from residues 144 to 448 showed about 17% identity with Δ^{15} (FAD3) (10) and Δ^{12} (FAD2) (10) desaturases from *Arabidopsis* and about 22% identity with a Δ^{6}-desaturase from the cyanobacterium *Synechocystis* (28). The whole sequence was also 60% identical to a cDNA clone of unknown function isolated from sunflower seeds (29). The three conserved histidine boxes that are characteristic of other membrane-bound desaturases were also present, and located at similar positions within the sequence. The distance between the first and second boxes was 32 aa, compared with 31 or 32 aa in Δ^{12}- and Δ^{15}-desaturases, and the distance between the second and third boxes was 172 aa, compared with 132–173 in other membrane-bound desaturases. The importance of these histidine boxes in catalysis has been demonstrated by site-directed mutagenesis of the soluble Δ^{9}-desaturase from rat and Δ^{12}-desaturase of *Synechocystis* (26, 30).

pBdes6 Encodes a Protein Containing a Cytochrome b_5-Like Heme-Binding Domain. The predicted hydrophobicity plot for the protein encoded by pBdes6 revealed a profile characteristic of a fatty acid desaturase, with the histidine boxes located in hydrophilic areas and separated by hydrophobic domains (not shown). The borage protein, however, contained a hydrophilic region at the N terminus longer than those of the membrane-bound Δ^{12}- and Δ^{15}-desaturases. Closer analysis showed significant sequence similarity between the first 90–100 aa at the N terminus of the protein encoded by pBdes6 and microsomal cytochrome b_5 proteins from higher plants (17). This similarity included the presence of seven of the eight invariant residues of the cytochrome b_5 class of proteins identified by Lederer (12). A heme-containing electron donor is required for fatty acid desaturation, and cytochrome b_5 is known to fulfill this function with membrane-bound fatty desaturases (Δ^{12} and Δ^{15}; refs. 8 and 13) and with the related Δ^{12}-hydroxylase (31). We therefore isolated a cDNA for cytochrome b_5 from the borage cDNA library using a tobacco cDNA (17) as a probe. Sequencing of this cDNA revealed an ORF encoding 132 aa which had some 80% sequence identity to cytochrome b_5 proteins from tobacco and rice (17). It also showed 32% sequence identity with the cytochrome b_5-related domain of the protein encoded by pBdes6 (Fig. 2). The identity is particularly high in regions previously identified as essential for cytochrome b_5 function, including the EHPGG motif in the heme-binding region.

Functional Analysis of pBdes6 in Transgenic Tobacco. To confirm the identity of pBdes6 as a Δ^{6}-fatty acid desaturase, the cDNA was transferred to tobacco plants under the control of an Ω-enhanced cauliflower mosaic virus 35S promoter via *Agrobacterium*-mediated gene transfer. Single leaves were removed from transformed and control plants, and FAMes were prepared from total lipid extracts and analyzed by GC (Fig. 3). Two peaks were observed in the chromatogram of

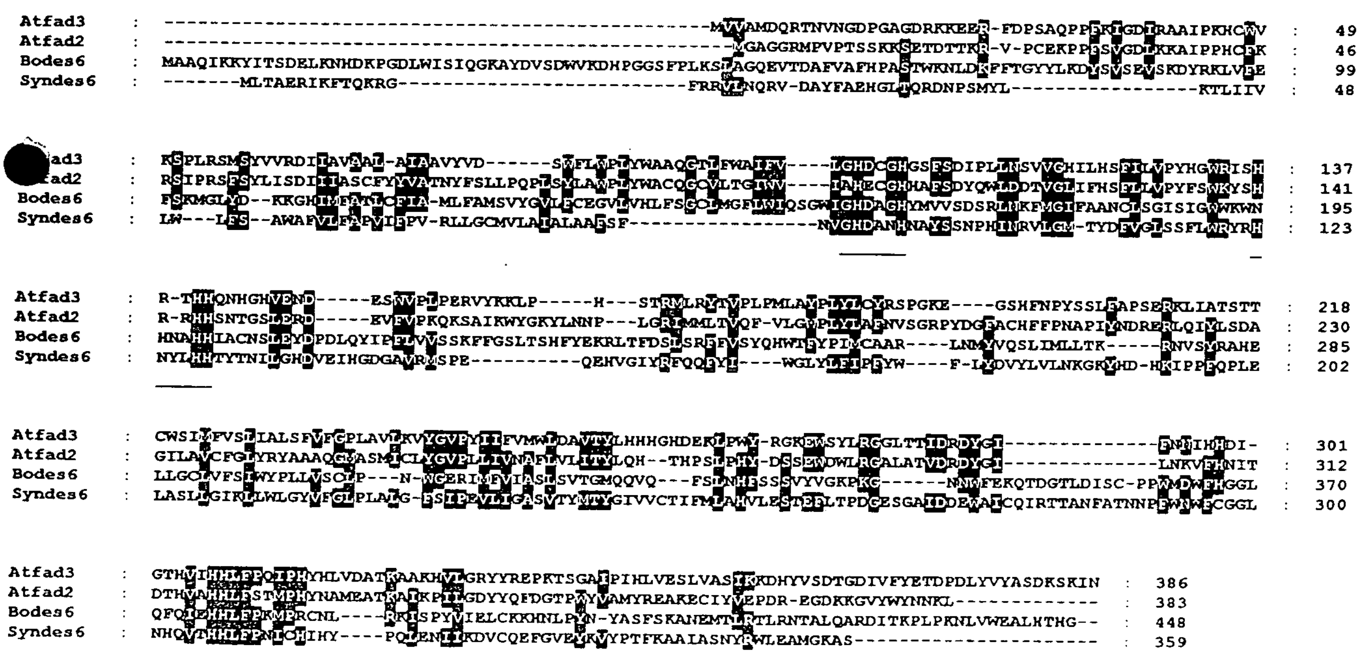

FIG. 1. Comparison of the deduced amino acid sequence of pBdes6 (labeled bodes6) with other desaturases. The entire coding sequence of pBdes6 was compared with the *Arabidopsis* FAD2 (atfad2) and FAD3 (atfad3) microsomal desaturases, as well as the cyanobacterial Δ^{6} desaturase (syndes6). Identical or conserved residues are boxed, and the conserved histidine boxes are underlined. The sequence of pBdes6 has been deposited in the GenBank database (accession no. U79010).

FIG. 2. Comparison of the deduced amino acid sequence of pBdes6 with plant cytochrome b_5 sequences. The first 196 residues of pBdes6 (bodes6) were compared with cytochrome b_5 sequences from borage (bocytb5), rice (oscytb5), and tobacco (ntcytb5). The conserved heme-binding domain is underlined. The sequence of borage cytochrome b_5 has been deposited in the GenBank database (accession no. U79011).

FAMes from the transformants (Fig. 3*B*) not present in the control plants (Fig. 3*A*). These peaks had retention times identical to the FAMe standards of GLA (C18:3 $\Delta^{6,9,12}$) and OTA (C18:4 $\Delta^{6,9,12,15}$). Further analysis of the transformant by GC-MS analysis of fatty acid DMOX derivatives confirmed the identities of these peaks (Fig. 4). Both spectra contained abundant m/z 113 (McLafferty rearrangement ion) and 126 peaks typical of fatty acid DMOX derivatives (23). The spectrum of the putative GLA derivative (Fig. 4*A*) had a molecular ion at m/z 331, suggesting an octadecatrienoic fatty acid; gaps of 12 amu between m/z 194 and 206, and m/z 234 and 246, indicating double bonds at C9 and C12; and a prominent m/z 166/167 pair specific for a C6 double bond (25). The spectrum of the putative OTA (Fig. 4*B*) had an additional gap of 12 amu between m/z 274 and 286, indicating the presence of a C15 double bond.

The proportions of fatty acids in the total lipid fractions prepared from the leaves of the control and transformed tobacco plants are given in Table 1. GLA and OTA account for about 13% and 10% of the total, respectively, in the transgenic material and are absent in the control plants. The presence of both GLA and OTA indicates that the Δ^6-desaturase used both linoleic acid and α-linolenic acid as substrates, and this may be responsible for the decrease in α-linolenic acid observed in the transgenic line.

Northern Blot Analysis. To provide further evidence that the introduction of the borage cDNA into the tobacco genome was responsible for these novel desaturation products, total RNA was isolated from the leaves of either a GLA-positive transgenic tobacco plant or a control plant that had been subject to the same tissue culture regime. RNA was also isolated from developing borage seeds and leaves, and the samples were analyzed by Northern blotting and probed with the pBdes6 cDNA (Fig. 5). A positive hybridization signal of identical mobility was obtained from RNA isolated from borage seeds and the transgenic GLA-positive tobacco line, but not from the control tobacco plant. Prolonged exposure of the autoradiograph showed that low levels of the pBdes6 transcript (or related transcripts) were present in the RNA samples extracted from borage leaves, a result that is consistent with the observed accumulation of GLA in the leaves of this species (9).

DISCUSSION

We undertook to isolate a cDNA encoding a Δ^6-desaturase from borage using a degenerate PCR approach based on conserved amino acid sequence motifs in other microsomal fatty acid desaturases (26, 30). Previous studies (9, 27) had shown that the borage Δ^6-desaturase activity was associated with the microsomal membrane fraction and probably used cytochrome b_5 as an electron donor, like the microsomal Δ^{12} (FAD2) and Δ^{15} (FAD3) desaturases. The borage cDNA

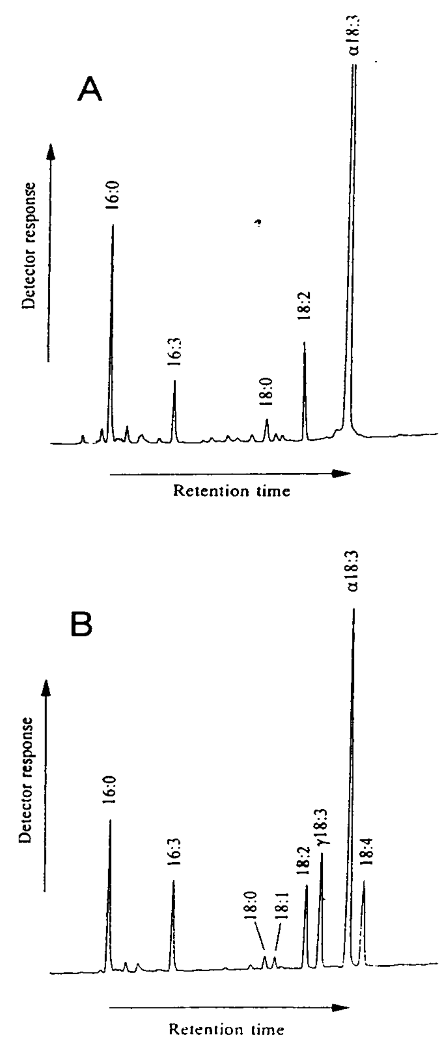

FIG. 3. Identification of GLA and OTA in transgenic tobacco by GC. Chromatograms of FAMes from leaf tissue of control tobacco plant (*A*) or plant transformed with pBdes6 (*B*). Two novel peaks are seen in *B*; these peaks have retention times identical to FAMe standards of GLA and OTA. The identity of peaks (as determined by comparison of retention times with those of known standards) is indicated. Detection was by flame ionization.

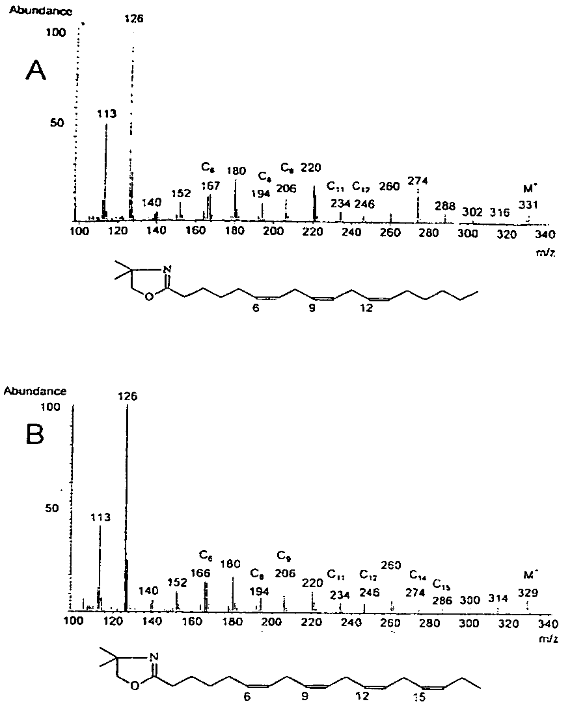

FIG. 4. Mass spectra of DMOX-derivatized fatty acids. Spectra of the fatty acids identified in Fig. 3 as GLA (*A*) and OTA (*B*). Details of the interpretation of the spectra are given in the text. The deduced structures of the fatty acid derivatives are shown.

clone (pBdes6) was confirmed to encode a Δ^6-desaturase by ectopic expression in the leaves of transgenic tobacco, resulting in the accumulation of the fatty acids GLA and OTA. The borage Δ^6-desaturase encoded by pBdes6 differed from previously characterized fatty acid desaturases from higher plants by the presence of an N-terminal extension related to the cytochrome b_5 class of heme-binding proteins (13). This domain is not present in the plant microsomal Δ^{12}- and Δ^{15}-desaturases (10, 11) or in the related Δ^{12}-hydroxylase (31) which have been cloned and functionally characterized in transgenic plants, although their use of microsomal cytochrome b_5 as an electron donor has been clearly demonstrated (8, 32). It is also clear that the N-terminal cytochrome b_5-related domain of pBdes6 is structurally distinct from the borage microsomal cytochrome b_5, as it does not contain the conserved hydrophobic C-terminal microsomal membrane anchor normally present in cytochrome b_5 proteins (17, 33). Since cytochrome b_5 usually functions in association with the

Table 1. Total fatty acid content of lipid extracts from leaves of a control tobacco plant and a plant transformed with the borage Δ^6 desaturase clone pBdes6

Acids		% Fatty acid	
		Control	Transformant
Palmitic	(C16:0)	16.3	14.0
Palmitoleic	(C16:1)	Trace	Trace
	(C16:3)	5.0	9.0
Stearic	(C18:0)	2.4	1.5
Oleic	(C18:1)	Trace	1.3
Linoleic	(C18:2)	9.1	9.5
γ-Linolenic	(C18:3)	ND	13.2
α-Linolenic	(C18:3)	65.1	40.1
OTA	(C18:4)	ND	9.6

Percentages were integrated from peak areas of GC traces shown in Fig. 3. ND, not detected.

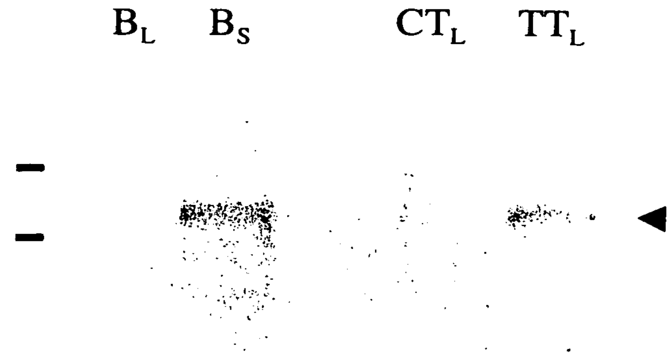

FIG. 5. Northern blot analysis of pBdes6 expression in borage and in transgenic tobacco. Total RNA (10 μg), extracted from borage leaves (B_L), borage seeds (B_S), control tobacco leaves (CT_L) or transgenic tobacco leaves (TT_L) was probed with ^{32}P-labeled pBdes6. After hybridization and high stringency washing, the resulting autoradiograph indicated expression of the pBdes6 transcript (≈2,000 bp; marked with the arrowhead) in borage seeds and transgenic tobacco leaves. The positions of the rRNA bands are indicated.

ER membrane, it is likely that the fusion protein described in this study has the same location and this is supported by the absence of any domains resembling chloroplast targeting transit sequences (34). Although the protein encoded by pBdes6 does not appear to have an N-terminal cleavable ER-targeting signal sequence (as judged by computer searching), the hydrophobic regions present in the protein would be sufficient to allow it associate with the endomembrane system. No obvious ER-retention motifs are present, but a potential glycosylation site is present at residues 278–280 (N-V-S).

Domains related to cytochrome b_5 are also present in a microsomal Δ^9-fatty acid desaturase (Ole1p, the OLE1 gene product) from yeast (35) and in other oxido/reductase enzymes (e.g., nitrate reductase, sulfite oxidase, and flavocytochrome b_2; ref. 12). In the yeast Δ^9-desaturase, this cytochrome b_5 domain exists as a 113-aa C-terminal fusion. Expression of OLE1 from a multicopy plasmid rescued yeast double mutants that lacked both OLE1 and microsomal cytochrome b_5 genes, unlike rescue by a rat microsomal Δ^9-desaturase, which required the presence of the cytochrome b_5 gene (35). Moreover, when the C-terminal b_5 domain of OLE1 was deleted, the yeast cells remained fatty acid auxotrophic, even in the presence of endogenous yeast cytochrome b_5, indicating that cytochrome b_5 is not able to act in trans to complement the loss of the cytochrome b_5 fusion domain of Ole1p (35). This suggests that the fusion domain plays an essential role in the desaturase reaction of this enzyme. A cDNA clone encoding a related cytochrome b_5 fusion protein has also been isolated from sunflower seeds (29), as noted above, but the corresponding protein has not been identified. In the sunflower protein, the cytochrome b_5 domain is fused to the N terminus of a putative desaturase sequence, as in the pBdes6 protein, and expression of this domain (≈120 residues) in *E. coli* (29) has shown that it is capable of undergoing reversible oxidation and reduction, indicating a functional heme group. Similar results were also obtained by expression of a tobacco cytochrome b_5 cDNA in *E. coli* (33). However, sunflower seeds do not accumulate GLA (3) and would therefore not be expected to possess an active Δ^6-desaturase. The substrate specificity of this sunflower protein is not known, and its role in fatty acid desaturation/hydroxylation-type reactions can only be inferred from sequence homology. Similarly, the functional and evolutionary significance of the existence of two types of membrane-bound desaturases in plants is not clear, although it can be suggested that the fusion of a cytochrome b_5 domain to the desaturase may facilitate a more efficient electron transfer. It is also

unclear why the yeast Ole1p desaturase has a C-terminal cytochrome b_5 domain, whereas the borage desaturase has an N-terminal cytochrome b_5 domain.

Recently, GLA and OTA accumulation in transgenic plants has been reported by Reddy and Thomas (36), who expressed a cyanobacterial Δ^6-desaturase gene in tobacco. The combined levels of GLA and OTA varied from about 2% to 4% of the leaf C:18 fatty acids, with only small differences depending on whether the protein was targeted to the plastid, cytoplasm, or ER lumen. This low level of activity is perhaps not surprising as the cyanobacterial Δ^6-desaturase differs from the ER-located higher plant desaturases in using ferredoxin rather than cytochrome b_5 as a cofactor. The cyanobacterial Δ^6-desaturase also resulted in the accumulation of comparatively higher levels of OTA than GLA, but the reason for this is not known. The levels of GLA and OTA accumulating in the leaves of transgenic tobacco plants expressing the borage desaturase encoded by pBdes6 account together for over 23% of total fatty acids, indicating the potential for producing GLA in transgenic oil crops. Sunflower would be particularly suitable in this respect as the presence of between 50% and 70% linoleic acid and with little or no α-linolenic acid (37) should facilitate the synthesis of high levels of GLA.

Lipids and Fatty Acids in Cyanobacteria

Cyanobacteria are autotrophic prokaryotes with the capacity for photosynthesis. Cyanobacterial cells resemble the chloroplasts of plants in terms of both membrane structure and glycerolipid composition (1). There are three types of membrane in cyanobacterial cells: the plasma membrane, the outer membrane, and the thylakoid membrane. The thylakoid membranes are closed systems and are separate from the plasma membrane (1,2). This architecture corresponds to that of the eukaryotic chloroplast, which has inner and outer envelope membranes and thylakoid membranes.

The major glycerolipids of cyanobacterial cells are monogalactosyl diacylglycerol (MGDG), digalactosyl diacylglycerol (DGDG), sulfoquinovosyl diacylglycerol (SQDG), and phosphatidylglycerol (PG) (2), and in eukaryotic chloroplasts these same glycerolipids predominate (3,4). MGDG accounts for about half of the total glycerolipids, and the other three glycerolipids contribute to the remaining half to different degrees, depending on the strain and specific growth conditions (5,6).

Cyanobacterial strains can be classified into four groups by reference to the unsaturation of fatty acids (Table 3.1). Group 1 is characterized by the presence of saturated and monounsaturated fatty acids excessively, whereas groups 2, 3 and 4 contain polyunsaturated fatty acids. The latter fatty acids are unusual in that the C_{18} and C_{16} fatty acids are esterified to the *sn*-1 and *sn*-2 positions of the glycerol moiety, respectively. Strains in group 1 [e.g., *Synechococcus* sp. PCC 7942 (*Anacystis nidulans* R2) and *Mastigocladus laminosus*] introduce a double bond only at the Δ9 position of fatty acids, either at the *sn*-1 or the *sn*-2 position (5,7). Strains in group 2 (e.g., *Synechococcus* sp. PCC 7002, *Anabaena variabilis*, *Plectonema boryanum*, and *Nostoc muscorum*) can introduce double bonds at the Δ9, Δ12 and Δ15 (ω-3) positions of C_{18} fatty acids at the *sn*-1 position, as well as at the Δ9 and Δ12 positions of C_{16} fatty acids at the *sn*-2 position (7,8). Strains in group 3 (e.g., *Synechocystis* sp. PCC 6714 and *Spirulina platensis*) can also introduce three double bonds, but these are found at the Δ6, Δ9 and Δ12 positions of C_{18} fatty acids at the *sn*-1 position (5). Strains in group 4 (e.g., *Synechocystis* sp. PCC 6803 and *Tolypothrix tenuis*) can introduce double bonds at the Δ6, Δ9, Δ12 and Δ15 (ω-3) positions of C_{18} fatty acids at the *sn*-1 position (5,9). However, desaturation at the *sn*-2 position in groups 1 and 2 and Δ6 desaturation at the *sn*-1 position in groups 3 and 4 are confined to MGDG, with both SQDG and PG being excluded. It is likely that desaturation does not

occur in fatty acids that are bound to DGDG; the various molecular species of DGDG are probably synthesized by galactosylation of the corresponding molecular species of MGDG (8). Among the members of the four groups of cyanobacteria, those in group 2 are the most similar to plant chloroplasts in terms of the desaturation of fatty acids.

Biosynthesis of γ-Linolenic Acid in *Spirulina*

The cyanobacterial strains in group 3 and group 4 synthesize γ-linolenic acid, while *Spirulina platensis*, which belongs to group 3, was found to contain the highest level of γ-linolenic acid among the strains examined (Table 3.1). We analyzed the fatty acid composition of individual lipid classes of *Spirulina platensis* (Table 3.2). The level of 16:0 ranged from 50 to 60% of the total fatty acids in each lipid class. γ-Linolenic acid was confined to MGDG and DGDG, whereas 18:2(9,12) was a main contributor of fatty acids to SQDG and DGDG.

The distribution of fatty acids at the *sn*-1 and *sn*-2 positions of the glycerol moieties of lipids (data not shown) indicated that the *sn*-2 position was exclusively esterified by 16:0, and that all of the C_{18} fatty acids and 16:1(9) were located at the *sn*-1 position. These findings suggest a pathway for the biosynthesis of fatty acids (or molecular species), as shown in Fig. 3.1. In MGDG, SQDG, and PG, the major precursors of all of the molecular species are *sn*-1-18:0/*sn*-2-16:0 species. In these precursors, the

t: Trace (less than 0.5%). *Mixture of Δ9-octadecenoic acid (oleic acid) and Δ11-octadecenoic acid (*cis*-vaccenic acid). F and U in parentheses indicate filamentous and unicellular strains, respectively.

TABLE 3.2 Major Fatty Acids of the Various Lipid Classes in *Spirulina platensis* Grown at 34°C

Lipid class	Fatty acid (mole %) 16:0	16:1 (9)	18:1 (9)	18:2 (9,12)	γ18:3 (6,9,12)
MGDG (47%)	52	3	1	1	42
DGDG (16%)	51	5	2	3	38
SQDG (17%)	60	2	7	26	1
PG (20%)	55	1	5	35	1

first double bond is introduced at the Δ9 position of 18:0, at the *sn*-1 position, to yield 18:1(9), and the second double bond is introduced at the Δ12 position of 18:1(9), at the *sn*-1 position, to yield 18:2(9,12). In SQDG and PG, no further desaturation occurs. In MGDG, by contrast, a third double bond is introduced at the Δ6 position of 18:2(9,12) to yield 18:3(6,9,12), in other words, γ-linolenic acid.

It is likely that the molecular species of DGDG are synthesized by galactosylation of the corresponding molecular species of MGDG and that no desaturation takes place in DGDG itself (8). The scheme in Fig. 3.1 suggests the possible existence of three different types of desaturase, namely, Δ9 desaturase, Δ12 desaturase and Δ6

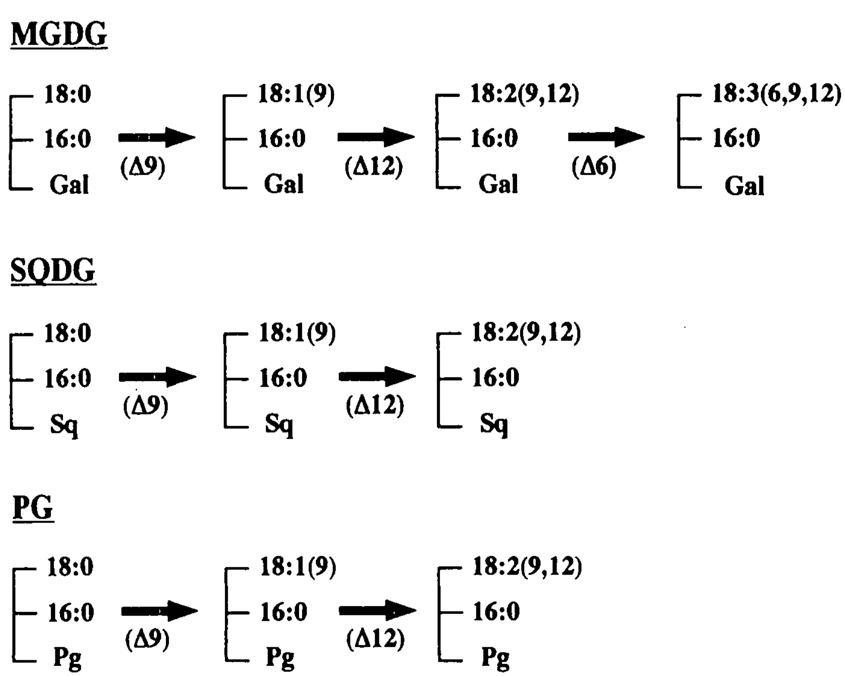

Fig. 3.1. Pathway for the desaturation of fatty acids in *Spirulina platensis*. Abbreviations: Gal, galactose; Sq, sulfoquinovose; Pg, glycerolphosphate

desaturase. This last desaturase is specific to MGDG, whereas the former two desaturases can use SQDG and PG as their substrates, in addition to MGDG.

There are three classes of desaturases. Acyl-CoA desaturases introduce double bonds into fatty acids bound to coenzyme A; these enzymes are bound to the endoplasmic reticulum in animal, yeast and fungal cells (10). Acyl-ACP desaturases introduce double bonds into fatty acids that are bound to ACP; they are present in the stroma of plant plastids (11). Acyl-lipid desaturases introduce double bonds into fatty acids that have been esterified to glycerolipids (12–14); they are bound to the endoplasmic reticulum, the chloroplast membrane in plant cells (12), and the thylakoid membranes in cyanobacterial cells (13). This last class of desaturase is the most efficient regulator of the extent of unsaturation of membrane lipids in response to changes in temperature.

The acyl-lipid desaturases can be further classified into two subgroups by reference to their electron donors. One subgroup, present in the endoplasmic reticulum of plant cells, uses cytochrome b_5 as the electron donor (15,16). The other, present in the chloroplasts of plant cells and in cyanobacterial cells, uses ferredoxin as the electron donor (13,17,18). A unique characteristic of the acyl-lipid desaturases is that they recognize, by an unknown mechanism, exactly those positions within various carbon chains at which double bonds are to be specifically introduced.

Cyanobacterial Desaturases

All known cyanobacterial desaturases are of the acyl-lipid and membrane-bound type (19). Because purification of these enzymes by conventional methods has proved difficult, we attempted the molecular cloning of the various desaturases. A mutant that was defective in the synthesis of 18:2(9,12), 18:3(6,9,12), 18:3(9,12,15), and 18:4(6,9,12,15) was initially isolated from *Synechocystis* sp. PCC 6803 after treatment of wild-type cells with ethyl methanesulfonate (9). The mutant, designated Fad12, was defective in desaturation at the Δ12 position of C_{18} fatty acids at the *sn*-1 position of the glycerol moiety in all lipid classes. The growth rate at 22°C of the mutant was much lower than that of the wild type, whereas mutant and wild-type cells grew at about the same rate at 34°C (20).

A gene (*desA*) for the Δ12 desaturase was isolated (21) by screening of the genomic DNA library of *Synechocystis* sp. PCC 6803 for the ability to complement the Fad12 mutation with respect to both growth at low temperature and desaturation at the Δ12 position of fatty acids after *in situ* transformation. The *desA* gene contains an open reading frame of 1053 bp that corresponds to 351 amino acid residues and encodes an acyl-lipid desaturase. The enzyme can introduce a second *cis*-double bond at the Δ12 position of fatty acids bound to membrane glycerolipids. Similar *desA* genes were isolated by heterologous hybridization from *Synechococcus* sp. PCC 7002, *Synechocystis* sp. PCC 6714 and *Anabaena variabilis* with a probe derived from the *desA* gene of *Synechocystis* sp. PCC 6803 (22). The amino acid sequence deduced from the nucleotide sequence of the *desA* gene of *Synechocystis* sp. PCC 6803 is similar to that of the gene from *Synechocystis* sp. PCC 6714. The extent of sequence similarity between the amino acid sequences from *Synechocystis*

sp. PCC 6803 and *Synechocystis* sp. PCC 6714 is 96%. However, the extent of conservation of the amino acid level between the sequences of polypeptides from *Synechocystis* sp. PCC 6803 and *Synechococcus* sp. PCC 7002 and that between the sequences of polypeptides from *Synechocystis* sp. PCC 6803 and *A. variabilis* are 57 and 59%, respectively (22).

The *desC* gene for a Δ9 acyl-lipid desaturase was found in the 5′-upstream region of the *desA* gene on the chromosome of *A. variabilis* (23). The *desC* gene of *Synechocystis* sp. PCC 6803 was cloned by screening a genomic library with a probe derived from the *desC* gene of *A. variabilis*. The deduced amino-acid sequences of the Δ9 acyl-lipid desaturases of *Synechocystis* sp. PCC 6803 and *A. variabilis* are similar to those of the Δ9 acyl-CoA desaturases from rat (24), mouse (25,26), and yeast (27), with homology at the amino acid level of about 25% in each case.

We have cloned the *desB* gene for the ω-3 acyl-lipid desaturase from *Synechocystis* sp. PCC 6803 by screening a genomic library with a probe derived from the *desA* gene of this strain (28). Reddy et al. (29) cloned the *desD* gene for Δ6 desaturase by the "gain-of-function" method using *Anabaena* sp. PCC 7120, which does not contain a Δ6 desaturase. Currently genes for all of the desaturases have been cloned from *Synechocystis* sp. PCC 6803.

Molecular Cloning of Desaturases of *Spirulina*

The desA *Gene for Δ12 Desaturase*

From comparisons of the sequences of the *desA* genes from *A. variabilis*, *Synechocystis* sp. PCC 6803, *Synechocystis* sp. PCC 6714 and *Synechococcus* sp. PCC 7002 (22), we selected two conserved regions, namely, amino acid positions 116–121 and 233–237, counted from the amino terminus of the *desA* gene of *Synechocystis* sp. PCC 6803. Oligonucleotides corresponding to these regions, including a synthetic *Eco RI* restriction site at each 5′ end, were synthesized. Their sequences were as follows:

> 5-GGGAATTCTA(TC)CC(ACGT)TT(TC)CA(TC)AG(CT)TGG-3′ and
> 5′-GGGAATTCAC(AG)TT(AGT)AT(AG)TC(AG)TG(AG)CA-3′.

The oligonucleotides were used as forward and reverse primers, respectively, for amplification by the polymerase chain reaction (PCR) of a partial nucleotide sequence of the *desA* gene of *Spirulina platensis*, with genomic DNA as the template. The amplified products of about 400 bp were of the size predicted for the partial sequence of the *desA* gene of *Synechocystis* sp. PCC 6803. These products of PCR were subcloned into pBluescript(SK+) (Stratagene, La Jolla, CA) and nucleotide sequences were determined. A clone with a sequence homologous to that of the *desA* gene of *Synechocystis* sp. PCC 6803 was identified. A genomic DNA library of *S. platensis*, constructed in the phage vector *λDASHII* (Stratagene) was screened with the insert of this clone, and the *desA* gene for Δ12 desaturase was cloned (its sequence has been deposited to the EMBL Data Library with the accession number X86736). Figure 3.2 shows a comparison of the amino acid sequence deduced from the *desA* gene of *S. platensis* with those deduced from the *desA* genes of *A. variabilis*, *Synechocystis* sp. PCC 6803, *Synechocystis* sp. PCC 6714 and *Synechococcus* sp. PCC 7002. The extent of homology at the amino acid level between the *desA* gene of *S. platensis* and those of *A. variabilis*, *Synechocystis* sp. PCC 6803, *Synechocystis* sp.

Fig. 3.2. Alignment of the amino acid sequence of the Δ12 desaturase of *Spirulina platensis* with those of Δ12 desaturases of *Anabaena variabilis*, *Synechocystis* sp. PCC 6803, *Synechocystis* sp. PCC 6714, and *Synechococcus* sp. PCC 7002 (22). Histidine residues conserved in the Δ12 desaturases are marked by asterisks. The histidine residues conserved in the Δ6, Δ9, Δ12, and Δ15 (ω-3) desaturases (19) are marked by double asterisks.

PCC 6714 and *Synechococcus* sp. PCC 7002 was calculated to be 56.5, 52.3, 52.3 and 57.2%, respectively. Seventeen histidine residues are conserved in the five Δ12 desaturases. Among them, eight histidine residues (Fig. 3.2) are conserved in the four desaturases that act at the Δ6, Δ9, Δ12, and ω-3 positions (19). As demonstrated in other enzymes with non-heme iron as the catalytic center, such as rubrerythrin (30), isopenicillin N synthase (31), stearoyl-acyl carrier protein desaturase (32), and lipoxygenase (33,34), it seems very likely that these histidine residues provide ligands to the iron that acts as the catalytic center.

The desD *Gene for Δ6 Desaturase*

The open reading frame (ORF) of the *desD* gene of *Synechosystis* sp. PCC 6803 was amplified by PCR with 5'-ATGCTAACAGCGGAAAGAAT-3' and 5'-GATGCTTTGCCCATGGCCTC-3' as the forward and reverse primers, respectively. The amplified product was subcloned into the TA cloning site of pCRII (Invitrogen, San Diego, CA). The genomic DNA library of *Spirulina platensis* that had been constructed in *λDASHII* was screened with a probe derived from the amplified DNA product, and the *desD* gene

Fig. 3.3. Alignment of the amino acid sequence of the Δ6 desaturase of *Spirulina platensis* with that of *Synechocystis* sp. PCC 6803 (29). Conserved histidine residues are marked by asterisks. The histidine residues conserved in the Δ6, Δ9, Δ12, and Δ15 (ω-3) desaturases (19) are marked by double asterisks.

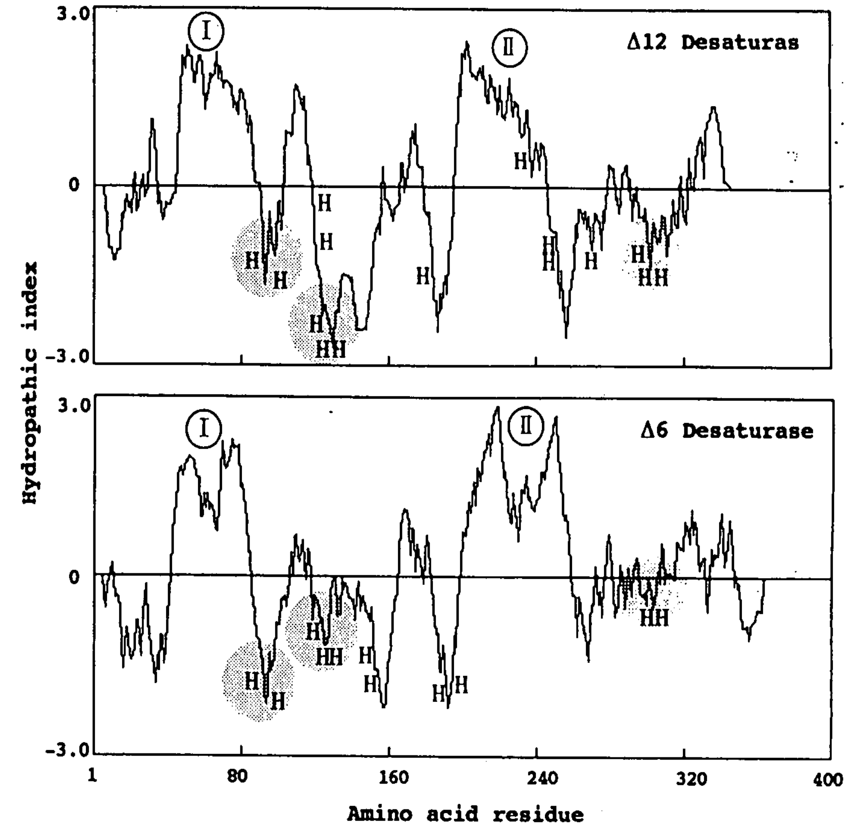

Fig. 3.4. Hydropathy plots and sites of histidine clusters in the Δ12 desaturase and Δ6 desaturase of *Spirulina platensis*. The three histidine (H) clusters conserved in the Δ6, Δ9, Δ12, and Δ15 (ω-3) desaturases (19) are shaded.

of *S. platensis* was cloned (its sequence has been deposited in the EMBL Data Library with the accession number X87094). Figure 3.3 shows the alignment of the deduced amino acid sequence of the Δ6 desaturase of *S. platensis* with that of *Synechocystis* sp. PCC 6803. The homology of the amino acid level between the two Δ6 desaturases is 52%, and 14 histidine residues are conserved in the two Δ6 desaturases. Seven of these histidine residues are conserved in all of the four desaturases that act at the Δ6, Δ9, Δ12, and ω-3 positions.

Figure 3.4 shows the predicted hydropathy profiles of the Δ12 and Δ6 desaturases of *S. platensis*. There are two hydrophobic domains, I and II, in both desaturases. It has been suggested that each domain spans the membrane twice, thus, each individual desaturase spans the membrane four times (19). Histidine residues are distributed throughout the sequences. However, the three histidine clusters conserved in all desaturases (19) are located at similar positions in both desaturases of *S. platensis*, and it seems likely that they are located on the cytoplasmic side of the membrane.

General Characteristics of *Spirulina platensis*

Spirulina platensis is a filamentous cyanobacterium, and its cells can be easily collected on nylon mesh. *S. platensis* grows under alkaline conditions with maximal growth at pH 10–11. These characteristics allow us to cultivate *S. platensis* in an open system and to collect the filamentous cells with a net, thereby freeing them of contaminating bacteria and fungi.

The history of *S. platensis* as a staple food for humans is of great interest (35). The cells contain a high proportion of protein (70% dry weight), several vitamins, and essential n-6 fatty acids. The strain that we used contains γ-linolenic acid, 18:3(6,9,12), as a major fatty acid. This compound has many pharmaceutical properties. It can relieve premenstrual syndrome (36) and is used as a treatment for a topic eczema. It also affects hyperlipidemia, which is frequently related to the development of arteriosclerosis and coronary heart disease, by lowering plasma levels of cholesterol and triglycerides.

Enzymatic Enrichment of γ-Linolenic Acid from Black Currant Seed Oil

H.-J. Wille and J. Wang

Nestlé Research Center,
Lausanne, Switzerland

Introduction

The biological importance of γ-linolenic acid (GLA, 6,9,12-octadecatrienoic acid) of the n-6 series is well known (1,2). GLA is a precursor in the synthesis of series 1 prostaglandins and is created in vivo by enzymatic desaturation of linoleic acid (9,12-octadecadienoic acid). Certain factors such as stress, poor nutrition and aging impair the effectiveness of the 6-desaturase enzyme responsible for this conversion. Dietary supplementation with GLA is able to by-pass this impediment in the metabolic process.

Natural sources of GLA contain variable amounts of this acid (Table 4.1) but this rarely exceeds 25% and is even lower for oils other than borage oil. Thus there has always been an interest in producing higher concentrates of GLA. Different fractionation techniques have been developed to enrich GLA from natural sources. These include urea fractionation of fatty acids (3–7), separation on Y-zeolite and lipase-catalyzed reactions, such as selective hydrolysis of GLA-containing triacylglycerols (8), and selective esterification of GLA-containing fatty acid mixtures (9) derived from borage or evening primrose oil.

This paper reports an investigation concerning the ability of enzymes which catalyze the esterification of fatty acids to discriminate between α- and γ-linolenic acid. Another

RESEARCH COMMUNICATION

Identification of a *Caenorhabditis elegans* Δ^6-fatty-acid-desaturase by heterologous expression in *Saccharomyces cerevisiae*

Johnathan A. NAPIER[1], Sandra J. HEY, Dominic J. LACEY and Peter R. SHEWRY
IACR-Long Ashton Research Station, Department of Agricultural Sciences, University of Bristol, Long Ashton, Bristol BS18 9AF, U.K.

We identified a cDNA expressed sequence tag from an animal (the nematode worm *Caenorhabditis elegans*) that showed weak similarity to a higher-plant microsomal Δ^6-desaturase. A full-length cDNA clone was isolated and expressed in the yeast *Saccharomyces cerevisiae*. This demonstrated that the protein encoded by the *C. elegans* cDNA was that of a fatty acid Δ^6-desaturase, as determined by the accumulation of γ-linolenic acid. The *C. elegans* Δ^6-desaturase contained an N-terminal cytochrome b_5 domain, indicating that it had a similar structure to that of the higher-plant Δ^6-desaturase. The *C. elegans* Δ^6-desaturase mapped to cosmid W08D2, a region of chromosome III. This is the first example of a Δ^6-desaturase isolated from an animal and also the first example of an animal desaturase containing a cytochrome b_5 domain.

INTRODUCTION

Over the last few years, a number of microsomal and soluble fatty acid desaturases have been isolated from higher plants, most notably *Arabidopsis thaliana* (thale cress). This has been achieved by a combined genetic and biochemical approach to the generation and complementation of mutant *Arabidopsis* lines defective in fatty acid desaturation or elongation [1]. The importance of this approach has been clearly validated by the isolation and characterization of genes encoding microsomal desaturases such the Δ^{12} [2] and Δ^{15} [3] (encoded by the *FAD2* and *FAD3* genes respectively) enzymes, which had previously proved intractable to classical purification techniques on account of their hydrophobicity. The isolation of these and related genes, such as the Δ^{12}-hydroxylase from *Ricinus communis* (castor bean) [4], has allowed the identification of a number of conserved motifs in plant microsomal desaturases, most notably the so called 'histidine boxes' [5]. These short motifs appear to be required for enzyme function and also allow the proteins containing these motifs to be classified as di-iron-centre-containing enzymes [6].

Recently we isolated a cDNA clone from borage (*Borago officinalis*), using highly degenerate PCR against these histidine motifs, which was shown by heterologous expression in transgenic tobacco (*Nicotiana tabacum*) to encode a microsomal Δ^6-desaturase [7]. Desaturation at the Δ^6 position is an unusual modification in higher plants, occurring only in a small number of species such as borage, evening primrose (*Oenothera* spp.) and redcurrant (*Ribes* spp.), which accumulate the Δ^6-unsaturated fatty acids γ-linolenic acid (GLA) and octadecatetraenoic acid in the seeds and/or leaves. GLA is a high-value plant fatty acid and is widely used in the treatment of a number of medical conditions, including eczema and mastalgia. It has been postulated that the application of GLA replaces the loss of endogenous Δ^6-unsaturated fatty acids [7]. The sequence of the borage microsomal Δ^6-desaturase differed from previously characterized plant microsomal desaturases/hydroxylases in that it contained an N-terminal extension which showed sequence similarity to cytochrome b_5, and also in that the third (most C-terminal) histidine box varied from the consensus [6] H-X-X-H-H, with a glutamine residue replacing the first histidine one.

Although Δ^6-fatty-acid desaturation is an unusual modification in higher plants, it is a common reaction in animals. The essential fatty acid linoleic acid ($C_{18:2,\Delta9,12}$) is desaturated to GLA by a Δ^6-desaturase as the first step on the biosynthetic pathway of the eicosanoids, which includes prostaglandins and leukotrienes. This results in the rapid metabolism of GLA [to dihomo-GLA ($C_{20:3,\Delta8,11,14}$) and arachidonic acid ($C_{20:4,\Delta5,8,11,14}$)], so accumulation of this fatty acid is not usually observed. For example, in the model animal system, the nematode *Caenorhabditis elegans*, polyunsaturated fatty acids which have been Δ^6-desaturated (in the form of arachidonic and eicosapentanoic acids) make up over 20% of the fatty acids of the total lipids, but no GLA is observed [8]. This is presumably due to its rapid elongation to C_{20} fatty acid derivatives.

We wished to determine whether the Δ^6-desaturase isolated from borage was representative of Δ^6-desaturases as a whole. Since most higher plants do not contain this enzyme [7], we decided to take advantage of the large amount of animal sequences available on public databases. To this end we identified a putative *C. elegans* Δ^6-desaturase expressed sequence tag (EST) and verified its function by expressing the corresponding cDNA in yeast. When the nematode coding sequence was expressed in yeast supplemented by the addition of linoleic acid, GLA was produced. This was confirmed by GC–MS, identifying the coding sequence similar to the *C. elegans* predicted open reading frame (ORF) W08D2.4 as a Δ^6-desaturase.

MATERIALS AND METHODS

The National Center for Biotechnology Information (NCBI) EST sequence database was searched for polypeptide sequences which were related to the higher-plant Δ^6-fatty-acid desaturase [7] and contained the variant histidine box Q-X-X-H-H. Putative positive *C. elegans* ESTs were further characterized by searching the *C. elegans* EST project database (http://www.ddbj.nig.ac.jp/

Abbreviations used: EST, expressed sequence tag; GLA, γ-linolenic acid; NCBI, National Center for Biotechnology Information; ORF, open reading frame.

[1] To whom correspondence should be sent.

htmls/c-elegans/html/ce-index.html) in order to identify related cosmid clones.

A partial cDNA clone identified by these searches was obtained from the *C. elegans* EST project (kindly supplied by Professor Y. Kohara, National Institute of Genetics, Mishima, Japan), and this was used to screen a *C. elegans* cDNA library (mixed stage; also supplied by Professor Y. Kohara) constructed in λZAPII. A number of positives were identified and further purified, and full-length clones were confirmed by sequencing to encode a transcript likely to have been transcribed from the gene designated W08D2.4, on cosmid W08D2, as determined by database searching of the genes sequenced by the *C. elegans* genome project.

The coding sequence of W08D2.4 was introduced into the yeast expression vector pYES2 by PCR. Oligonucleotides with 5′ overhangs were used to introduce *Kpn*I and *Sac*I sites at the 5′ and 3′ ends respectively. The fidelity of the construct was checked by *in vitro* transcription and translation using the *TnT* system (Promega).

The resulting plasmid was introduced into yeast (*Saccharomyces cerevisiae*) by the lithium acetate method [9], and expression of the transgene was induced by addition of galactose. The yeast was supplemented by the addition of 0.2 mM linoleate in the presence of 1 % tergitol, following the method of [10].

Yeast total fatty acids were analysed by GC of methyl esters, exactly as described previously [7]. Confirmation of the presence of GLA was carried out by GC–MS using a Kratos MS80RFA instrument operating at an ionization voltage of 70 eV, with a scan range of 500–40 Da. The mass spectrum of the novel peak resolved by GC was compared with that of an authentic GLA standard (Sigma).

RESULTS

The sequence of the borage Δ^6-desaturase was used to search databases for related sequences in species which, although they do not accumulate GLA, might be expected to perform Δ^6-desaturation. The simplest organism which fulfilled this criterion was the free-living nematode *C. elegans*. This small animal has been subject to both random cDNA (EST) sequencing programs and large-scale genome sequencing. Our searches of EST databases identified a high-scoring nematode EST, namely yk436b12. This partial sequence of 448 bases was used to search for related cosmid clones sequenced by the Japan *C. elegans* genome project, using the DNA database of the Japan *C. elegans* EST project server. This indicated that the clone yk436b12 showed sequence similarity to part of a gene present on cosmid W08D2 (GenBank accession number Z70271), which forms part of chromosome III [11]. Bases 21–2957 of cosmid W08D2 are predicted by the protein prediction program Genefinder [11] to encode an ORF of 473 residues which is interrupted by five introns. Examination of this predicted protein sequence (designated W08D2.4 by the Sanger Centre Nematode Sequencing Project, Hinxton, Saffron Walden, Essex, U.K.) revealed that it had a number of characteristics reminiscent of a microsomal fatty acid desaturase, including three histidine boxes. However, the predicated protein sequence indicated the presence of an N-terminal domain similar to that of cytochrome b_5, containing the diagnostic H-P-G-G motif found in cytochrome b_5 proteins [12]. Since the Δ^6-desaturase isolated by us from borage [7] also contained an N-terminal b_5 domain, this indicated that W08D2.4 may encode a Δ^6-desaturase. Closer examination of the sequence revealed the presence of the variant third histidine box, with a H → Q substitution (again as observed in the borage Δ^6-desaturase). However, the similarity between W08D2.4 and the borage Δ^6-desaturase is low (51.7 %), as is the value of 31.0 % for identity. Since W08D2.4 was encoded by a gene containing many introns, it was necessary to isolate a full-length cDNA to verify the sequence predicated by the Genefinder program [11] and also to allow the expression of the ORF to define the encoded function.

A cDNA library and EST yk436b12 were generously provided by Professor Y. Kohara, and a number of positive plaques were identified by screening with the EST insert. These were further purified to homogeneity, excised, and the largest inserts (~

Figure 1 A comparison of the deduced amino acid sequences of the borage (*B. officinalis*) Δ^6-desaturase [7] and the *C. elegans* cDNA CeD6.1

Abbreviations: Ceeld6, CeD6.1; Boofd6, borage Δ^6-desaturase.

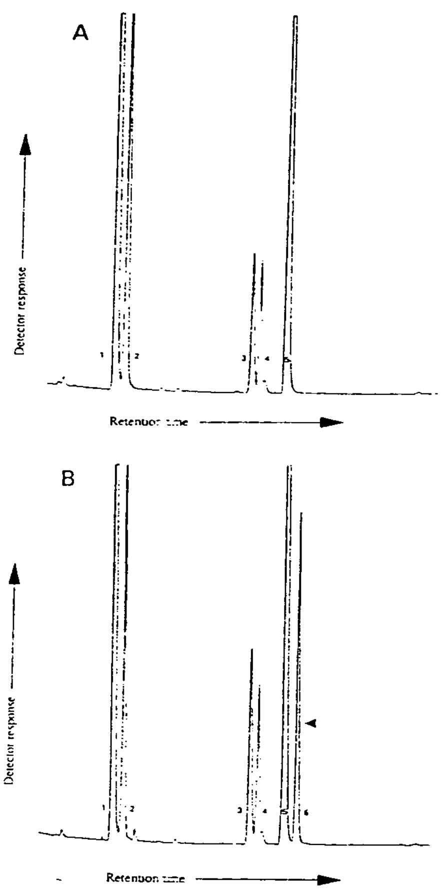

Figure 2 **Identification of GLA in transgenic yeast by GC**

[illegible] esters of total lipids of *S. cerevisiae* grown under inducing conditions (linoleate [illegible]) were analysed by GC, using flame-ionization detection. (**A**) is yeast transformed [illegible] empty) vector pYES2 and (**B**) is transformed with pYCeD6.1. The common peaks [illegible] as $C_{16:0}$ (peak 1), $C_{16:1}$ (peak 2), $C_{18:0}$ (peak 3), $C_{18:1}$ (peak 4) and $C_{18:2}$ (peak [illegible] exogenously). The additional peak (peak 6 in **B**), which corresponds to the retention time of GLA, is indicated by the arrowhead.

1450 bp) from the resulting rescued phagemids were sequenced. This confirmed that the cDNAs isolated by us did indeed show [illegible] to W08D2.4, with the 5′ and 3′ ends of the cDNA [illegible] equivalent to bases 9 and 3079 of the sequence of cosmid W08D2. Since the ATG initiating coding predicted by the Genefinder program to be the start of gene product W08D2.4 was indeed the first methionine residue in the cDNA clone, we reasoned that we had isolated a *bona fide* full-length cDNA. One representative cDNA clone (termed Cede.1; 1463 bp in length) was sequenced on both strands (Genbank ID: AF031477); the deduced amino acid sequence is identical with that predicted for W08D2.4 over the majority of the protein. However, DNA [illegible] encoding residues 38–67 (Y-S-I...L-Y-F) predicted for W[illegible] are not present in the cDNA clone. This means that the deduced amino acid sequence of pCeD6.1 is in fact 443 amino acids long, as opposed to that predicted for W08D2.4, which is 473 residues in length. The only other difference between the two amino acid sequences is an M → V substitution at residue 401, resulting from a A → G base change (base 1211). The deduced amino acid sequence of CeD6.1 is shown in Figure 1, compared with the previously characterized borage Δ^6-desaturase [7]. Note the presence in the *C. elegans* sequence of the H-P-G-G cytochrome b_5 motif in the N-terminus (encoded by bases 96–108) and the H → Q substitution in the third histidine box (encoded by bases 1157–1172).

Clone pCeD6.1 was then used as a template for PCR amplification of the entire predicated coding sequence (443 amino acid residues in length) and cloned into the yeast expression vector pYES2 (Invitrogen) to yield pYCeD6. The fidelity of this PCR-generated sequence was checked by *in vitro* transcription/translation of the plasmid, using the T_7 RNA polymerase promoter present in pYES2. Using the Promega *TnT*-coupled transcription/translation system, translation products were generated and analysed by SDS/PAGE and autoradiography, following the supplier's instructions. This revealed (results not shown) that the plasmid pYCeD6 generated a product of molecular mass 55 kDa, whereas the control (pYES2) failed to yield any protein products, indicating that the construct was correct.

Transformation and selection of yeast able to grow on uracil-deficient medium revealed yeast colonies carrying the recombinant plasmid pYCeD6 by virtue of the URA3-selectable marker carried by pYES2. Expression of pYCeD6 was obtained by inducing the GAL promoter which is present in pYES2. This was carried out after the cells had been grown up overnight with raffinose as a carbon source, and the medium supplemented by the addition of linoleate ($C_{18:2,\Delta9,12}$) in the presence of low concentrations of detergent. This latter addition was required since the normal substrate for Δ^6-desaturation is $C_{18:2}$ fatty acid, which does not normally occur in *S. cerevisiae*. The cultures were then allowed to continue to grow after induction, with aliquots being removed for analysis by GC. When methyl esters of total fatty acids isolated from yeast carrying the plasmid pYCeD6, grown in the presence of galactose and linoleate, were analysed by GC, an additional peak was observed (Figure 2). This had the same retention time as an authentic GLA standard, indicating that the transgenic yeast was capable of desaturating linoleic acid at the Δ^6 position. No such peaks were observed in any of the control samples (transformation with pYES2). The identity of this extra peak was confirmed by GC–MS, which positively identified the compound as GLA (Figure 3). This confirms that Cede.1 encodes a *C. elegans* Δ^6-desaturase, and that this cDNA is likely to be transcribed from the gene predicted to encode ORF W08D2.4, though the deduced amino acid sequence of Cede.1 is 30 residues smaller than that of W08D2.4.

DISCUSSION

Organisms such as *C. elegans* perform Δ^6-desaturation, but unlike plants such as borage or evening primrose, they do not accumulate Δ^6 unsaturated fatty acids such as GLA. We provide evidence that a *C. elegans* cDNA (Cede.1) encodes a Δ^6-desaturase, and that this sequence is similar to the predicted ORF W08D2.4, except for a 30-residue insertion present in the N-terminal region of the latter protein. Whether the deduced amino acid sequence predicted for Cede.1 represents a splicing variant of W08D2.4, or is a result of a misprediction of the intron/exon junctions by the Genefinder program is unclear. However, it is clear that Cede.1 encodes a Δ^6-desaturase. The ORF encoded by this *C. elegans* sequence appears to be related to the higher-plant Δ^6-fatty-acid desaturase previously isolated by us [7], in that they both contain N-terminal domains which show similarity to cytochrome b_5. In contrast, other microsomal fatty acid desaturases from plants do not contain this domain and use free cytochrome b_5 as an electron donor [1,13,14]. Similarly, the domain is absent from the only fatty acid

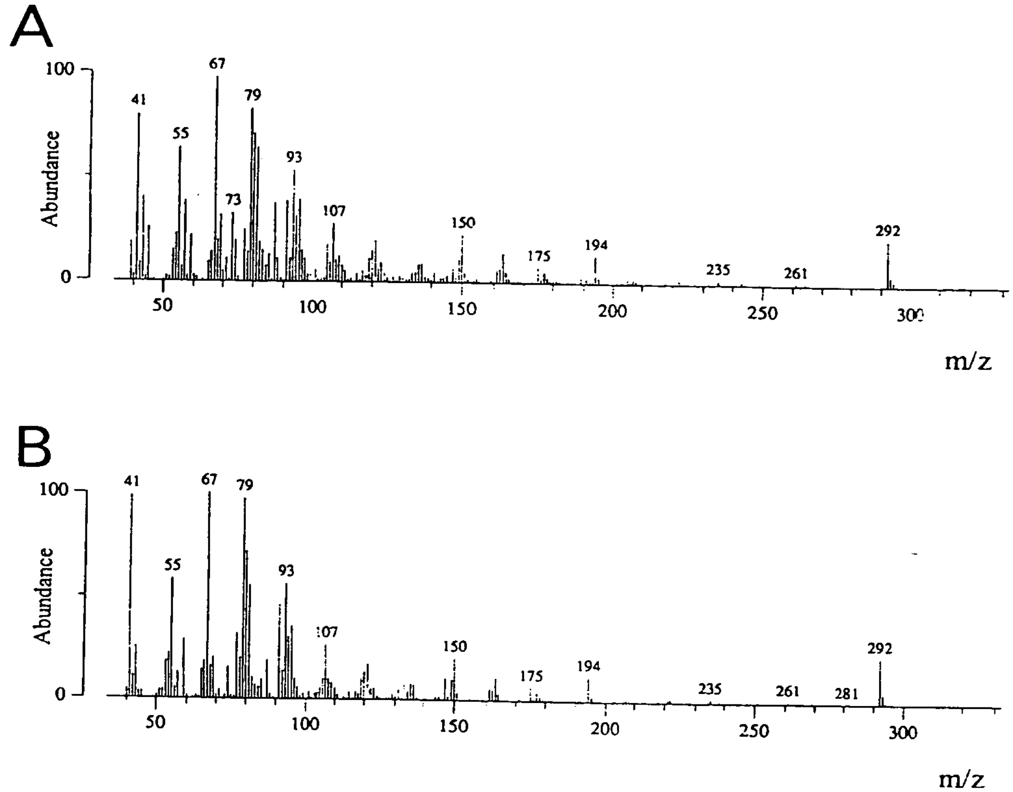

Figure 3 GC–MS analysis of the novel peak identified in yeast carrying pYCeD6.1

The sample was analysed for mass spectra as described previously [7], and the data were used to search a library of profiles. The sample was identified as GLA. A comparison of the mass spectra of the novel peak (**A**) and an authentic GLA standard (**B**) is shown. Visual- and computer-based inspection indicates that the two spectra are identical.

desaturases isolated from animals, a desaturase from *C. elegans* which recognizes a range of C_{18} and $C_{20,\omega-6}$ substrates [15] and a putative fatty acid desaturase from man (*Homo sapiens*) [16]. These animal sequences also differ from the borage and *C. elegans* Δ^6-desaturases in lacking the variant histidine box.

The reason why the Δ^6-desaturases have a fused cytochrome b_5 domain is not known [17]; the only other examples of desaturases with this extension are fungal microsomal (OLE1) Δ^9-desaturases [10] in which the domain is fused to the C-terminus rather than the N-terminus of the protein. However, the borage Δ^6-desaturase differs from all the other characterized plant microsomal desaturases in carrying out 'front-end' desaturation, which is the introduction of a double bond between C-3 and C-7 of an already unsaturated fatty acid [18]. This means the enzyme desaturates at positions between the carboxy group and pre-existing double bonds, whereas other plant enzymes desaturate sequentially towards the methyl group. It will be of interest to determine whether this feature is shared by other 'front-end' desaturases of plant and animal origin. It is also clear that identification of heterologous fatty acid desaturases will be facilitated by the yeast expression system described in the present study.

We are very grateful to Professor Yuji Kohara for supplying nematode ESTs and cDNA libraries. We thank Mervyn Lewis for carrying out the GC–MS analysis. IACR-Long Ashton Research Station receives grant-aided support from the Biotechnology and Biological Sciences Research Council (U.K.).

Summary

The moss *Physcomitrella patens* contains high levels of arachidonic acid. For its synthesis from linoleic acid by desaturation and elongation, novel Δ5- and Δ6- desaturases are required. To isolate one of these, PCR-based cloning was used, and resulted in the isolation of a full-length cDNA coding for a putatively new desaturase. The deduced amino acid sequence has three domains: a N-terminal segment of about 100 amino acids, with no similarity to any sequence in the data banks, followed by a cytochrome b_5-related region and a C-terminal sequence with low similarity (27% identity) to acyl-lipid desaturases. To elucidate the function of this protein, we disrupted its gene by transforming *P. patens* with the corresponding linear genomic sequence, into which a positive selection marker had been inserted. The molecular analysis of five transformed lines showed that the selection cartridge had been inserted into the corresponding genomic locus of all five lines. The gene disruption resulted in a dramatic alteration of the fatty acid pattern in the knockout plants. The large increase in linoleic acid and the concomitant disappearance of γ-linolenic and arachidonic acid in all knockout lines suggested that the new cDNA coded for a Δ6-desaturase. This was confirmed by expression of the cDNA in yeast and analysis of the resultant fatty acids by GC–MS. Only the transformed yeast cells were able to introduce a further double bond into the Δ6-position of unsaturated fatty acids. To our knowledge, this is the first report of a successful gene disruption in a multicellular plant resulting in a specific biochemical phenotype.

Intr duction

Compared to higher plants, many members of moss, algae and fern families produce a wider variety of polyunsaturated fatty acids (PUFA; Dembitsky, 1993; Jamieson and Reid, 1975; Zhukova and Aizdaicher, 1995), and PUFA such as arachidonic acid (AA) and eicosapentaenoic acid (EPA) are produced only by lower plants. The function of these long-chain PUFA in the membranes of lower plants is still unclear, whereas in humans, they play a key role in eicosanoid metabolism (Samuelsson, 1983).

The biosynthesis of AA and EPA generally starts with linoleic acid (18:2), which is channelled into a widely branching network of desaturation and elongation steps (Arao and Yamada, 1994; Cohen *et al.*, 1995; Shiran *et al.*, 1996). Key enzymes in this network are Δ5- and Δ6-desaturases, which introduce the new double bond between the first double bond and the carboxyl terminus of the fatty acid, known as carboxyl-directed desaturation. This mode differs from the methyl-directed desaturation, which works towards the methyl end of the unsaturated fatty acid. Desaturases of both types belong to the membrane-bound desaturases, which operate in microsomes or in plastids (Heinz, 1993). All desaturases, including acyl-ACP, (Ohlrogge *et al.*, 1993), acyl-CoA (Enoch *et al.*, 1976) and acyl-lipid desaturases, are believed to catalyse an O_2-dependent reaction, in which either cytochrome b_5 serves as electron donor for the microsomal or ferredoxin for the plastidial desaturases (Kearns *et al.*, 1991; Schmidt and Heinz, 1990; Smith *et al.*, 1990).

In the last few years, extensive sequence information from various desaturases in the methyl-directed group has been accumulated, but only a few from the carboxyl-directed group (Reddy *et al.*, 1993; Sayanova *et al.*, 1997) have been cloned so far. A good source to clone new desaturases is the moss *Physcomitrella patens*. Lipids of *P. patens* contain high proportions of AA (up to 30% of total fatty acids) indicating strong expression of Δ5- and Δ6-desaturases (Grimsley *et al.*, 1981). This moss can be propagated vegetatively in the haploid state (Ashton and Cove, 1977), which simplifies the phenotypic analysis after mutation or transformation (Schaefer *et al.*, 1991). Genes of this organism can be specifically inactivated by gene targeting, as shown by Schaefer and Zrÿd (1997), who demonstrated that integration of homologous DNA into the genome of *P. patens* takes place by homologous recombination with a relative efficiency of more than 90% among transgenic plants.

In the present communication, we describe the isolation of a new cDNA and its corresponding genomic sequence from *P. patens*, using a PCR-based screening. The encoded protein shared less than 27% sequence identity with known desaturases and represents a fusion between a C-terminal

desaturase with a cytochrome b_5-related part and a N-terminal extension. Its function and importance for the biosynthesis of AA (20:4) was identified by disrupting the corresponding gene in *P. patens*. The biochemical phenotype of the null mutant and its subsequent complementation by feeding γ-linolenic acid ($18{:}3^{\Delta 6,9,12}$) demonstrated that the disrupted gene codes for a Δ6-desaturase, which plays a key role in the synthesis of 20:4.

Results

PCR-based cloning

For PCR experiments, different sets of degenerate primers, deduced from the three conserved histidine boxes of acyl-lipid desaturases, were synthesized (Avelange-Macherel *et al.*, 1995; Shanklin *et al.*, 1994). The template used was single-stranded cDNA from *P. patens*, which was reverse-transcribed from mRNA of 12-day-old protonema cultures. Bands of the expected length were cloned and sequenced. Data bank searches and alignments with these new sequences indicated similarities to acyl-lipid desaturases for seven cDNA fragments. Six of them were classified as putative members of the well-known Δ12- and Δ15-desaturases based on high identities of over 60%. In contrast to this, one sequence of 550 bp showed less than 27% identity to known desaturases. Since *Physcomitrella* was expected to express Δ5- and Δ6-desaturases, it was postulated that this sequence might be derived from one of those desaturases.

Isolation of a full-length cDNA

To isolate a full-length cDNA clone, the 520 bp PCR fragment was DIG-labelled, and used to screen a cDNA library of 12-day-old protonemta. Of 3.0×10^5 plaques screened, 19 positives were isolated. The restriction analysis of their inserts showed a similar pattern in all cases. The partial sequence analysis from six inserts revealed that they were identical to each other within their overlapping regions and also to the original 520 bp PCR fragment. The longest insert, designated *PPDES6* cDNA, was sequenced on both strands. It had a length of 2012 bp excluding its poly(A) tail. An open reading frame stretched from position 319–1894, and several stop codons in the corresponding 5′ untranslated region indicated its full length (Figure 1). The protein PPDES6 translated from the *PPDES6* cDNA contained 525 amino acid residues with a calculated molecular weight of 59.3 kDa. This is 7–20 kDa larger than all acyl-lipid desaturases known from higher plants and cyanobacteria. Data bank searches indicated similarity to cytochrome b_5 sequences from residues 105–176 and to desaturases from residue 207 towards the C-terminus.

The desaturase domain showed the highest similarity to the cytochrome b_5-containing fusion protein of *Helianthus annuus* (Sperling *et al.*, 1995), a putative fusion protein from *Caenorhabditis elegans* encoded by cosmid T13F2 (Z81122) and the Δ6-desaturases of *Spirulina platensis* (X87094), *Borago officinalis* (Sayanova *et al.*, 1997) as well as *Synechocystis* sp. PCC 6803 (Reddy *et al.*, 1993). The identity values of PPDES6 to these proteins were low and ranged from 21% to 27% for the sequence between the first and third histidine boxes and from 12% to 23% over the entire length. The sequence motive QIEHH of the third histidine box started with a glutamine instead of a histidine, which has also been found in Δ6-desaturases and the cytochrome b_5 fusion protein of *H. annuus*, but not in other membrane-bound desaturases. The hydrophobicity plot (Kyte and Doolittle, 1982) after residue 200 showed the typical profile of membrane-bound desaturases (data not shown). The cytochrome b_5-related domain contained the eight invariant residues typical for the cytochrome b_5 superfamily (Lederer, 1994).

The N-terminal extension of about 100 residues did not share significant similarity to any sequence in the data banks, and computer analysis did not detect any motives for protein targeting or modification either for the extension or for the whole protein.

Structure of the gene

To knock out the *PPDES6* gene, its genomic sequence was amplified by PCR with specific primers C and D. Primer C was deduced from the 5′ end and D from the middle of the 3′ untranslated region of the *PPDES6* cDNA. PCR with these primers and genomic DNA of *P. patens* as template amplified a fragment that was 1578 bp longer than the distance between the binding sites of the primers on the cDNA. The genomic PCR fragment, denoted *PPDES6*, was cloned and sequenced on both strands (Figure 2). Apart from six putative introns (i1-i6) it was 100% identical with the cDNA, confirming its identity as the genomic locus of the *PPDES6* cDNA. The 5′ splicing border of five introns was GT and the 3′ border of all six was AG. Only the fourth intron i4 contained the unusual 5′ splicing border GC, which has been found in genes of several plant species (Xue and Rask, 1995). The reliability of this intron sequence was confirmed by sequencing two other PCR-amplified clones over this region. The intron i4 was located between two triplets coding for residues 176 and 177. After residue 176 the detected similarity to cytochrome b_5 sequences was terminated.

Gene targeting

For the disruption experiments, the first histidine box of the genomic clone was replaced by the *npt* II gene as a positive selection marker. The subsequent double digestion

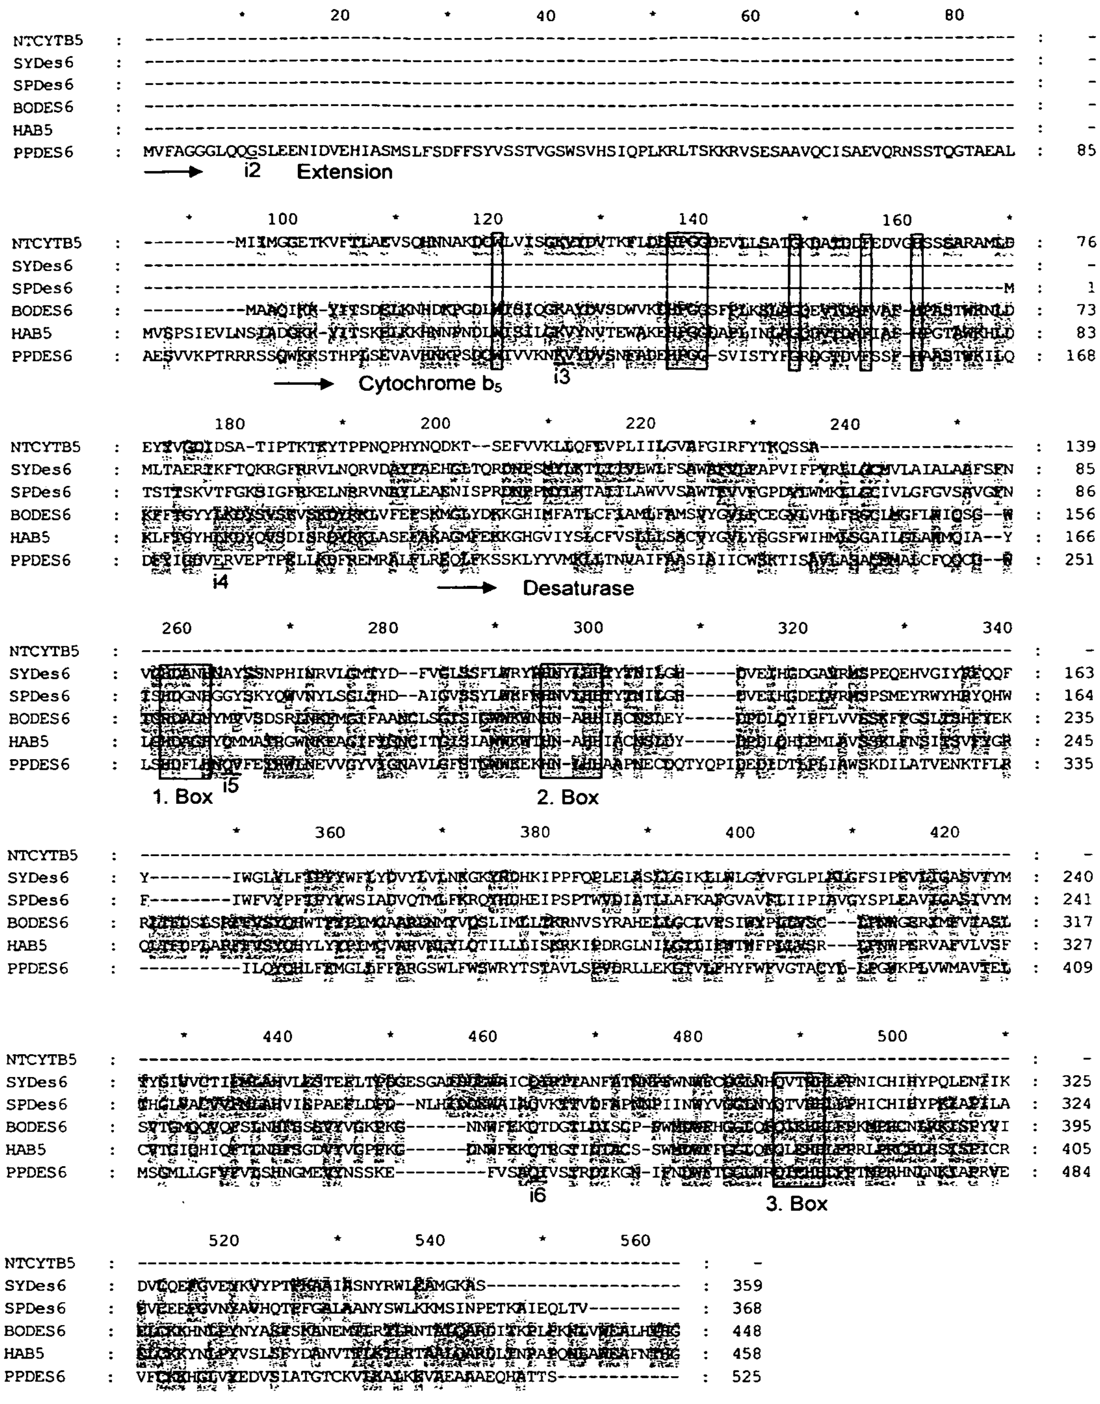

Figure 1. Amino acid sequences of PPDES6 and closely related proteins.
For alignment the CLUSTAL X program was used (gap opening 10, gap extension 0.05). Conserved and invariant residues are grey. The approximate beginning of the three domains from PPDES6 are marked by arrows and their putative function. The eight invariant residues characteristic for the cytochrome b_5 superfamily and the three histidine boxes of the desaturase domains are framed. The underlined residues indicate the positions of introns i1–i6 in the genomic sequence *PPDES6*. SYDes6, SPDes6 and BODES6 refer to the Δ6-desaturases of *Synechocystis* (U79010), *Spirulina* (X87094) and *Borago* (U79010). NTCYTB5 and HAB5 refer to the cytochrome b_5 of *Nicotiana* (X71441) and the b_5 fusion protein of *Helianthus* (X87143), respectively.

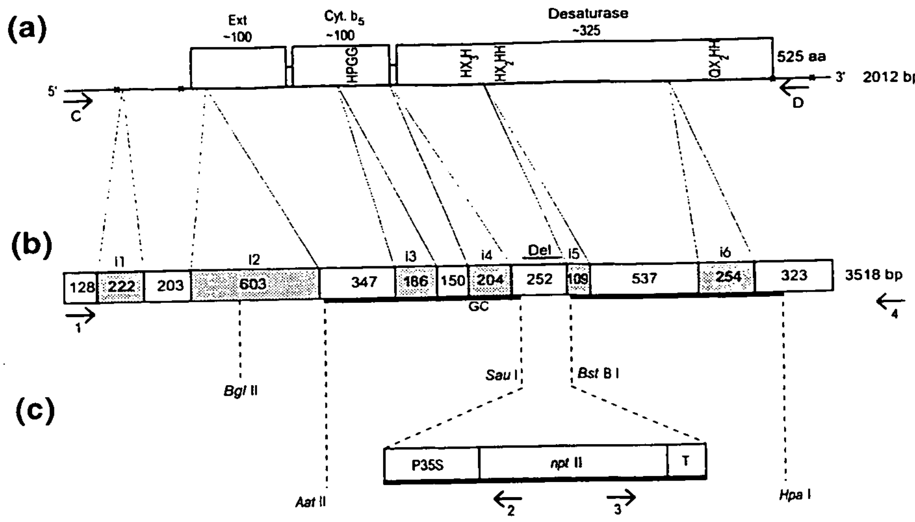

Figure 2. Structure of the desaturase cDNA (a), the desaturase gene (b) and the fragment used for gene disruption (c).
(a) *PPDES6* cDNA (2012 bp) and schematic representation of the protein PPDES6 (525 aa) with three domains: an extension (Ext) of unknown function, a cytochrome b_5- and a desaturase-like region with typical amino acid blocks. Stop codons are symbolized by stars.
(b) Corresponding genomic sequence *PPDES6* amplified with primer C and D (shown in a). The positions and lengths of the six introns (i1–i6, grey) are marked. The GC splice junction is shown for i4.
(c) Replacement fragment for gene disruption: the first histidine box in the genomic fragment was substituted after a *SauI*/*BstBI* double digestion by the *npt* II cartridge, which contained the *npt* II coding region between the CaMV 35S promoter (P35S) and terminator (T). The transformation was carried out after linearization with *AatII* and *HpaI* resulting in a linear fragment (underlined in bold) with the *npt* II cartridge inserted into the sequence of the desaturase. The numbered arrows below the blocks indicate the binding sites of primers used for subsequent PCR analyses. The localization of the Del probe used for Southern blotting (see Figure 3) is marked with a line above the block.

with *SauI*/*BstBI* yielded a linear fragment with the *npt* II gene in its centre and the desaturase arms at both ends (Figure 2). This linear fragment was used to transform *P. patens* protoplasts by the PEG method (Schaefer *et al.*, 1991). Seven transformation experiments with 3.0×10^5 protoplasts in each experiment resulted in the isolation of 56 independent and stably transformed lines. Five randomly selected transgenic lines (K1–K5) were used for detailed analysis regarding the molecular biology of gene disruption as well as its consequences for fatty acid biosynthesis.

Molecular analysis of the transgenic lines

The specific integration of the transformed DNA into the *PPDES6* gene was analysed by PCR using genomic DNA from five transformed lines (K1–K5) and the wild type. The locations of the different primers are presented in Figure 2. It is important to point out that the 3′ end of primer 4 binds 40 bp downstream of the cloned genomic sequence to exclude PCR signals resulting from contamination by the DNA used for transformation. Its sequence was derived from the 3′ end of an incomplete cDNA clone, which showed the same sequence in the overlapping region with cDNA *PPDES6*, but contained a longer 3′ end.

PCR with the primer pair 1/2 amplified fragments of 2.7 kbp, and with the primer pair 3/4 bands of 1.6 kbp, from all five transformants, whereas experiments with the wild type gave negative results. The length of the bands agreed with a substitution of the first histidine box of the *PPDES6* gene by the *npt* II cassette. Both PCR fragments from two transformants (K2 and K3) were cloned and partially sequenced. The sequenced segments were identical with the corresponding regions of the transformed gene disruption construct. Most important, the fragments from primer pair 3/4 contained the downstream genomic element of 40 bp, which was absent in the transformed DNA. They lacked the first histidine box, and the transition regions of the *npt* II cassette to the *PPDES6* gene, as well as the regions containing the restriction sites *Aat* II and *Hpa* I, were identical in their sequence with the disruption construct.

To provide evidence for a deletion of the first histidine box in the *PPDES6* gene of the transgenic lines, the genomic DNA of the transformed lines and the wild type was digested with *BglII*, blotted and hybridized with the DIG-labelled deletion probe Del. This probe represents the *SauI*/*BstBI* fragment encoding the first histidine box, which had been deleted from the transformed disruption construct (Figure 3). Hybridization with the deletion probe Del showed one strong signal of 4.5 kbp and two very weak signals of 5.0 and 7.0 kbp with the wild type DNA. The transformed lines K1–K4 had lost the strong 4.5 kbp signal but not the two weak signals. Line K5 corresponded to the

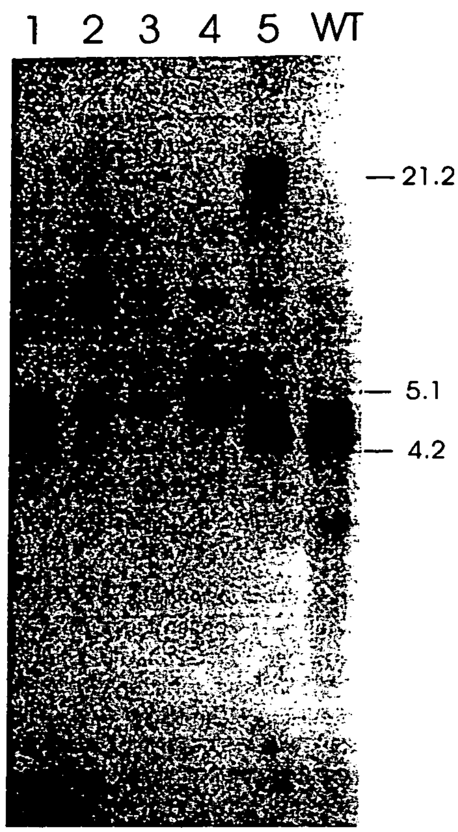

Figure 3. Verification of gene disruption by Southern blotting.
Genomic DNA (4 μg) from the wild type (WT) and five transformed lines K1–K5 (1–5) was digested with *Bgl*II and hybridized with the deletion probe (Del). The location of the probe is described in Figure 2. Molecular weights in kbp are indicated on the right.

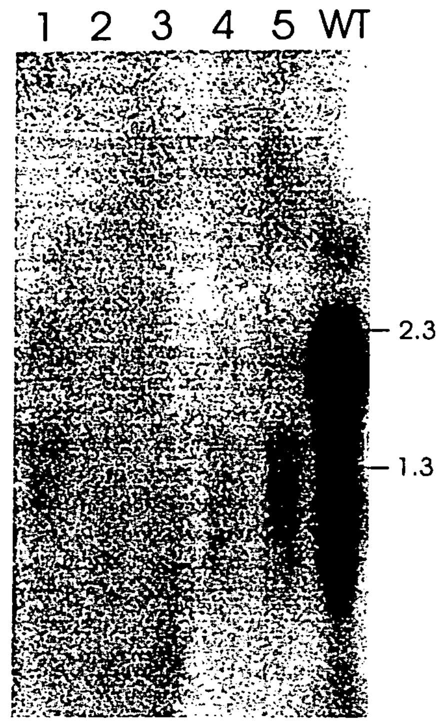

Figure 4. Northern blot analysis of *PPDES6* expression.
Total RNA (20 μg) from 14-day-old *P. patens* protonemata was probed with an RNA probe transcribed from the last 600 bp of the *PPDES6* cDNA. Five transgenic lines K1–K5 (1–5) and the wild type (WT) were analysed. Molecular weights in kb are indicated on the right.

wild type situation but contained an additional band of more than 21 kbp.

To compare the expression of *PPDES6* in the five transgenic lines with the wild type, we blotted total RNA of 14-day-old protonemata and hybridized it with a DIG-labelled RNA probe against the 3′ end of the *PPDES6* cDNA (Figure 4). The wild type showed a strong signal of 2.0–2.2 kb, whereas the five transgenic lines had lost this transcript. Hybridization with a *npt* II-specific probe (blot not shown) detected a strong signal of 1.0–1.3 kb in all transgenic lines but not in the wild type.

Functional analysis of PPDES6 in P. patens

For the functional identification of the desaturase, we analysed the total fatty acids of the wild type and the five knockout lines. The fatty acid analyses presented in Figure 5 are confined to the wild type and to line K2, but the other four lines tested gave essentially the same results. Pathways [1] and [2] below show the sequences proposed for the biosynthesis of AA (20:4) and EPA (20:5) in *P. patens*, and they are supported by our results (fatty acids are indicated as $m{:}n^{\Delta a,b,c,\ldots}$; m refers to the number of carbon atoms, n to the double bonds and $^{\Delta a,b,c,\ldots}$ to the position of the double bonds; desaturation and elongation steps are indicated by Δx and EL).

$$18{:}2^{\Delta 9,12} \xrightarrow{\Delta 6} 18{:}3^{\Delta 6,9,12} \xrightarrow{EL} 20{:}3^{\Delta 8,11,14} \xrightarrow{\Delta 5} 20{:}4^{\Delta 5,8,11,14} \quad [1]$$

$$\downarrow \Delta 15$$

$$18{:}2^{\Delta 9,12,15} \xrightarrow{\Delta 6} 18{:}4^{\Delta 6,9,12,15} \xrightarrow{EL} 20{:}4^{\Delta 8,11,14,17} \xrightarrow{\Delta 5} 20{:}5^{\Delta 5,8,11,14,17} \quad [2]$$

Compared with the wild type, all transgenic lines showed a strong decrease in those unsaturated fatty acids, the formation of which involves a Δ6-desaturation step (Figure 5): $18{:}3^{\Delta 6,9,12}$, $18{:}4^{\Delta 6,9,12,15}$, $20{:}3^{\Delta 8,11,14}$, $20{:}5^{\Delta 5,8,11,14,17}$ and most clearly $20{:}4^{\Delta 5,8,11,14}$. On the other hand, the possible substrates for a Δ6-desaturase, $18{:}2^{\Delta 9,12}$ and $18{:}3^{\Delta 9,12,15}$, increased. Therefore, it is most likely that the reactions from $18{:}2^{\Delta 9,12}$ to $18{:}3^{\Delta 6,9,12}$ as well as from $18{:}3^{\Delta 9,12,15}$ to $18{:}4^{\Delta 6,9,12,15}$ were blocked, both of which are catalysed by a Δ6-desaturase (compare pathways [1] and [2]).

To provide further evidence for the function of the new

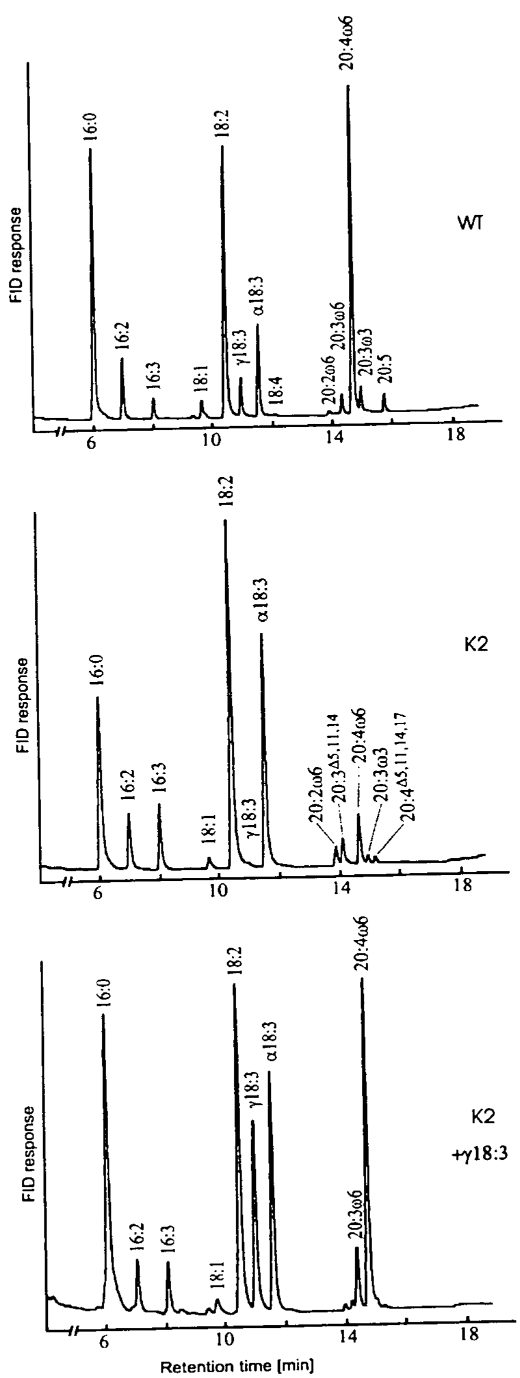

Figure 5. Fatty acid profiles of the *P. patens* wild type (WT) and the knockout line K2. The fatty acid methyl esters (FAME) of the total lipids were analysed by capillary gas-liquid chromatography. The chromatograms WT and K2 show the FAME of protonemata grown for 14 days in liquid medium. The lower chromatogram shows the FAME profile of K2 cells cultured under the same conditions but in the presence of 50 μM of γ18:3 ($18{:}3^{\Delta6,9,12}$).

Δ6-desaturase, we supplemented the knockout line K2 and the wild type with $18{:}3^{\Delta6,9,12}$ (γ18:3). In K2 the feeding of this fatty acid resulted in the reappearance of $20{:}3^{\Delta8,11,14}$ and $20{:}4^{\Delta5,8,11,14}$, whereas almost no change was observed in the wild type. This experiment indicates that the knockout line K2 is able to synthesize 20:4 from added $18{:}3^{\Delta6,9,12}$, but not from $18{:}2^{\Delta9,12}$, which increases in unsupplemented K2. However, the addition of $18{:}3^{\Delta6,9,12}$ did not result in a complementation of the almost complete disappearance of $20{:}5^{\Delta5,8,11,14,17}$ in K2.

The addition of $20{:}2^{\Delta11,14}$ and $20{:}3^{\Delta11,14,17}$ (data not shown) did not result in an increase of 20:4 and 20:5 in the wild type or in K2. Another interesting effect of the knockout was the completely different proportion of C20-fatty acids in K2 (7%) compared to the wild type (30%).

Functional expression of PPDES6 in Saccharomyces cerevisiae

To exclude the possibility that the loss of a Δ6-desaturase in the knockout lines is a consequence of a regulatory difference between the *Physcomitrella* wild type and knockout lines, *PPDES6* was functionally expressed in *Saccharomyces cerevisiae*. Plasmid pYESΔ6 containing the open reading frame of the *PPDES6* cDNA was transformed into the *S. cerevisiae* strain INVSC1. One clone transformed with pYESΔ6 and another with the empty vector pYES2 as control were grown for four to five generations after induction with 2% galactose in minimal medium. Since *S. cerevisiae* does not contain the dienoic fatty acid substrates required for a Δ6-desaturase, the expression was performed with supplementation of $18{:}2^{\Delta9,12}$ and $18{:}3^{\Delta9,12,15}$, respectively. In subsequent analyses of total fatty acids, the following Δ6-desaturated products were detected in the strain expressing PPDES6: $16{:}2^{\Delta6,9}$, $18{:}2^{\Delta6,9}$, $18{:}3^{\Delta6,9,12}$ and $18{:}4^{\Delta6,9,12,15}$ (Table 1). In the control cells, none of these fatty acids were detected. The production of these fatty acids with an additional Δ6-double bond confirmed that cDNA *PPDES6* encodes a Δ6-fatty acid desaturase.

Discussion

Structural properties

The cDNA and the genomic sequence *PPDES6* encoding a novel Δ6-desaturase from *P. patens* were cloned using a PCR-based approach. The deduced protein shared less than 27% identity with the recently cloned Δ6-desaturase from *B. officinalis* and with the Δ6-desaturases from cyanobacteria (Reddy *et al.*, 1993; Sayanova *et al.*, 1997). This is a surprisingly low value, as until now all desaturases of the same regioselectivity and the same subcellular compartment have been more highly conserved, even between distantly related organisms. For example, six

Table 1. Expression of the Δ6-desaturase in *S. cerevisiae*. The fatty acid methyl esters of the total lipids from cells transformed with pYES2 (WT control) and pYESΔ6 (Δ6-desaturase of *P. patens*) were analysed by GLC. The cells were cultured in minimal medium supplemented with 2% galactose for 24 h at 30°C. The last two columns show data from cultures supplemented with $18{:}2^{\Delta 9,12}$ (18:2) and $18{:}3^{\Delta 9,12,15}$ (α18:3)

other PCR fragments from *P. patens*, isolated in this screening, coded for putative Δ12- and Δ15-desaturases and displayed more than 60% identity to the corresponding desaturases of higher plants and cyanobacteria.

The presence of the cytochrome b_5-related domain upstream of the desaturase suggests its localization in microsomes rather than in chloroplasts, because plastidial desaturases normally use ferredoxin as electron donor (Heinz, 1993). Besides this, PPDES6 contains a new N-terminal extension of about 100 amino acids, which is absent in other presently known desaturases. The function of this extension is unclear, since it shows no significant homology to any known protein, and targeting or modification signals were not detected. Interestingly, the three histidine boxes and the cytochrome b_5 domain of PPDES6 are encoded by separate exons (Figure 2), implying that they may constitute separate evolutionary units. The fourth intron containing the unusual 5′ splicing border GC is located directly after the last triplet for the cytochrome b_5 domain. This organization could allow a differential splicing between the 5′ border of the first and the 3′ border of the fourth intron, resulting in a deletion of both the cytochrome b_5 domain and the N-terminal extension from the desaturase domain of the *PPDES6* transcript.

Molecular analysis of the transgenic lines

In this study, we have described the highly efficient knockout of the *PPDES6* gene after transforming *P. patens* with a linear disruption fragment. PCR experiments proved the specific integration of the *npt* II cassette into the *PPDES6* locus in all arbitrarily chosen transgenic lines. Furthermore, Southern blot experiments confirmed the deletion of a 200 bp segment encoding the first histidine box from the genome of four transgenic lines (K1–K4). It is likely that reciprocal exchange by double cross-over led to the integration observed in these four lines. Targeting experiments from Schaefer and Zrÿd (1997) demonstrated homologous integration into a locus but not a substitution. The blots with line K5 reveal an even more complicated situation. Nevertheless, K5 does not express the Δ6-desaturase activity any more. Two additional signals of low intensity in wild type and in all transgenic lines indicated that related genomic sequences were not involved in the gene targeting events. The presence of these sequences suggests that isoforms of other Δ6-desaturases could be expressed to some extent in the knockout lines.

In the Northern blots all transgenic lines showed a dramatically reduced expression of *PPDES6* while this transcript was abundant in the wild type. Thus loss of desaturase activity, as evident from the fatty acid profiles most probably resulted from loss of transcription due to gene disruption.

Functional analysis of PPDES6 in P. patens *and* S. cerevisiae

The gene disruption of *PPDES6* resulted in a dramatic alteration of the fatty acid pattern in the transformed lines. The knockout lines showed an increase of 18:2 and α18:3 and a decrease of Δ6-desaturated fatty acids. Therefore, it is likely that *PPDES6* codes for a Δ6-desaturase, which desaturates $18{:}2^{\Delta 9,12}$ to $18{:}3^{\Delta 6,9,12}$ and $18{:}3^{\Delta 9,12,15}$ to $18{:}4^{\Delta 6,9,12,15}$. The Δ6-regioselectivity of PPDES6 was further verified by restoration of 20:4 biosynthesis upon feeding of γ18:3 (Figure 5). The synthesis of 20:4 from γ18:3 would not work if a Δ5-desaturase or the elongation system had been blocked. The Δ6-desaturation of 18:2 and α18:3 added to *S. cerevisiae* cells expressing PPDES6 confirmed these results and excluded the possibility that the loss of a Δ6-desaturase in the knockout lines was due to regulatory alterations, for example the loss of an activator for the Δ6-desaturase. On the other hand, we could not detect a Δ8-C20-desaturase in *P. patens*, since addition of $20{:}2^{\Delta 11,14}$ and $20{:}3^{\Delta 11,14,17}$ did not increase the content of 20:4 and 20:5. A Δ8-desaturase operating at the C20-level could theoretically replace the Δ6-C18-desaturase in the biosynthesis of 20:4 and 20:5. Such an enzyme has been suggested to be present in *Euglena gracilis* (Nichols and Appleby, 1969).

Based on the knockout effects and feeding experiments, we propose the two pathways [1] and [2] mentioned above for the biosynthesis of 20:4 and 20:5 in *P. patens*, which branch at 18:2. They are in agreement with the biosynthesis of 20:4 and 20:5 as suggested for *Porphyridium cruentum* (Shiran *et al.*, 1996).

It should be noted that *S. cerevisiae* cells expressing PPDES6 produced not only $18{:}3^{\Delta6,9,12}$ and $18{:}4^{\Delta6,9,12,15}$, but also $16{:}2^{\Delta6,9}$ and $18{:}2^{\Delta6,9}$, which were not detected in *P. patens*. The reason for their absence in *P. patens* may be the low content and rapid turn-over of the putative precursors, $16{:}1^{\Delta9}$ and $18{:}1^{\Delta9}$, in the moss, whereas they are produced in high amounts by *S. cerevisiae*. Since the Δ6-desaturase converts $16{:}1^{\Delta9}$ to $16{:}2^{\Delta6,9}$, but does not introduce a Δ8-double bond into $20{:}2^{\Delta11,14}$ and $20{:}3^{\Delta11,14,17}$ (mentioned above), the insertion of the Δ6-double bond involves measuring from the carboxy terminus (and the Δ9-double bond) rather than from the methyl end. This classifies the desaturase as a Δ6-desaturase (Heinz, 1993).

Another interesting effect is the significant decrease in C20-fatty acids in the knockout lines. The decrease from more than 30% in the wild type to less than 7% in K2 indicates that the elongation system of *P. patens* prefers or even requires Δ6-desaturated C18-fatty acids. This elongation process is either very rapid or channelled and thus prevents the accumulation of γ18:3 or 18:4 in lipids. In the other organisms, from which Δ6-desaturases have been cloned (*B. officinalis* and *Synechocystis*), elongation systems do not co-operate with this desaturase and therefore Δ6-desaturated fatty acids can accumulate. A detailed analysis of lipids and fatty acids in *P. patens* wild type and knockout plants, as well as in *S. cerevisiae* expressing the Δ6-desaturase, will be published elsewhere (T. Girke *et al.*, manuscript in preparation).

In our present study, all knockout lines still contained small amounts of fatty acids, which were synthesized by a pathway requiring Δ6-desaturase. This indicates that at least one other functional gene for a Δ6-desaturase should exist. Possible candidates may be the two faint signals observed above the targeted 4.5 kbp fragment in Southern blots of wild type and transgenic lines (Figure 3).

Apart from these biochemical changes, we did not detect any visibly altered phenotype in the knockout plants, at least in their protonema or gametophore states at 25°C. Therefore, it was not possible at this point to evaluate the physiological importance of 20:4 for the moss. The appearance of a visible phenotype may also be prevented by residual 20:4. Deletions of several desaturases in *Synechocystis* became critical only if the Δ6- and Δ12-desaturase were knocked out together, whereas a reduction in trienoic acids without affecting dienoic acids was not critical (Tasaka *et al.*, 1996).

Experimental procedures

Plant material and culture conditions

The protonemata of *Physcomitrella patens* (Hedw.) BSG were grown in liquid medium (Reski *et al.*, 1994). For feeding experiments with fatty acids, 4-day-old cultures were supplemented with ammonium salts of fatty acids (dissolved in ethanol) to a final concentration of 50 μM and further cultivated for an additional 6–8 days.

Analysis of nucleic acids

DNA manipulations were performed according to standard protocols (Sambrook *et al.*, 1989) unless otherwise stated. DNA sequences were determined on both strands by the dideoxy chain termination method using Dye Primer as well as Dye Terminator sequencing kits.

PCR with degenerated primers and cDNA library screening

Poly(A)$^+$ RNA was isolated with Dynabeads (Dynal, Oslo, Norway) from total RNA of 12-day-old *P. patens* protonema cultures, and reverse-transcribed into single-stranded cDNA. This ss-cDNA was used as template in the PCR-based cloning. A 550 bp PCR fragment was amplified with the degenerate sense primer A 5′-TGGTGGAA(A/G)TGGA(C/A)ICA(T/C)AA-3′ and antisense primer B 5′-GG(A/G)AA(A/T/G/C)A(A/G)(G/A)TG(G/A)TG(C/T)TC-3′ derived from the amino acid sequence WWKW (N/T)HN and EHHLFP, respectively. The PCR reactions were carried out with Taq DNA polymerase using an amplification programme of 3 min denaturation at 94°C, followed by 30 cycles of 20 sec at 94°C, 30 sec at 45°C, 1 min at 72°C and terminated by 5 min extension at 72°C. The PCR fragments of the expected length (500–600 bp) were cloned in pUC18 and sequenced. A digoxygenin-labelled DNA probe of the PCR fragment was synthesized by PCR and used to screen a lambda ZAPII cDNA library of 12-day-old protonemata according to the manufacturer's protocols (Boehringer, Mannheim, Germany; Stratagene, La Jolla, CA). The longest insert (*PPDES6* cDNA) was sequenced on both strands using overlapping subclones. The corresponding genomic sequence *PPDES6* was isolated by PCR with specific primers C (5′-CCGAGTCGCGGATCAGCC-3′) and D (5′-CAGTACATTCGGTCATTCACC-3′) using the Expand High Fidelity PCR System (Boehringer) and the hot start PCR program described below. *PPDES6* was cloned into the pCR-Script Amp SK(+) cloning vector (Stratagene), resulting in plasmid p*PPDES6* and sequenced on both strands.

Transformation of P. patens

First the vector pRT101neo was constructed to obtain a *npt* II selection cassette, which could be excised by *Hin*dIII digestion. For this purpose the *npt* II coding region of pRT100neo (Töpfer *et al.*, 1993) was excised with *Hin*dIII (blunted)/*Xho*I and ligated between the CaMV 35S promoter and terminator of pRT101 (Töpfer *et al.*, 1987), which had been digested with *Xba*I (blunted)/*Xho*I. The gene disruption construct resulted from the substitution of a *Sau*I/*Bst*BI fragment in the genomic clone p*PPDES6* by the *npt* II selection cartridge. Subsequently, the disruption construct was digested with *Aat*II and *Hpa*I, resulting in a linear fragment with the *npt* II gene in its centre flanked by genomic sequences of 923 bp and 1159 bp. Fifteen micrograms of this linear DNA were phenol extracted, precipitated and used for the transformation without separation from the vector. PEG-mediated direct DNA transfer into protoplasts was performed as described by Schaefer *et al.* (1991). The regenerated protonemata were selected for 14 days on medium with G418 (50 mg l^{-1}), released for 12 days under non-selective conditions and again grown for 14 days on

selection plates. Well growing plants surviving this selection regime were defined as stable transformants and cultivated for mass production in non-selective liquid medium. The stability of their G418 resistance was tested every 4 weeks by incubating aliquots on selection plates.

DIG-labelling of DNA and RNA

DNA probes were labelled with digoxygenin by PCR (PCR DIG probe synthesis kit; Boehringer). The 5′ ends of the primers for the deletion probe (Del) were located on the *PPDES6* cDNA at position 910 and 1092 (*SauI*/*BstBI* fragment). The desaturase RNA probe was transcribed by *in vitro* transcription with digoxygenin (Boehringer) from a subclone of the *PPDES6* cDNA containing the last 600 bp of its 3′ end and the *npt* II probe from a subclone coding for the *npt* II.

PCR detection, Southern and Northern blot analysis

Four primers were used in the PCR experiments for the detection of gene targeting events. Primer 1 was derived from the 5′ end of *PPDES6*. Primers 2 and 3 were constructed from the ends of the *npt* II coding region. The sequence of primer 4 (5′-CAGAGACGAATCGTGGCTCC-3′) was derived from the 3′ end of an incomplete cDNA clone, which was identical with *PPDES6* cDNA in the overlapping region, but contained a longer 3′ end. The PCR experiments with these primers were run with a hot start programme of 10 min denaturation at 94°C, addition of the polymerase at 72°C, followed by 30 cycles of 30 sec at 94°C, 30 sec at 60°C, 3 min at 72°C and terminated by 10 min extension at 72°C. Genomic DNA of *P. patens* was extracted with cetyl-trimethyl-ammonium bromide according to Rogers and Bendich (1988). Four micrograms of DNA were digested with the appropriate restriction enzyme, separated on a 0.7% agarose gel by electrophoresis, transferred onto a nylon membrane and hybridized. The final washing steps were performed in 0.5 × SSC with 0.1% SDS at 68°C. The detection was accomplished with a chemiluminescent substrate (CSPD, Boehringer). The Northern blot experiments were performed with total RNA isolated from 14-day-old protonema cultures (RNeasy plant kit, Qiagen, Hilden, Germany). Twenty micrograms of total RNA were separated on a standard formaldehyde gel, blotted onto a nylon membrane and hybridized with RNA probes. The final washing steps were performed in 0.1 × SSC with 0.1% SDS.

Expression in S. cerevisiae

The open reading frame of the *PPDES6* cDNA was cloned behind the galactose-inducible promotor *GAL1* of the yeast expression vector pYES2 (Invitrogen, Leek, Netherlands). For this purpose, a new *XhoI* site was introduced by PCR (32 bp upstream from its deduced translational start at position 319). The entire open reading frame of the desaturase was released with *HindIII* (blunted)/*XhoI* and ligated into the *XbaI* (blunted)/*XhoI* sites of the pYES2 vector to yield plasmid pYESΔ6. Its sequence was verified by DNA sequencing. The plasmids pYESΔ6 and pYES2 were transformed into the *Saccharomyces cerevisiae* strain INVSC1 (Invitrogen) by the lithium acetate method (Ausubel *et al.*, 1995). Cells harbouring the plasmids pYES2 and pYESΔ6 were grown in complete minimal drop-out uracil medium (CMdum) containing 2% raffinose as the exclusive carbon source (Ausubel *et al.*, 1995; Kajiwara *et al.*, 1996) and 1% Tergitol NP-40 (w/v; Sigma) for the solubilization of fatty acids (Avery *et al.*, 1996). For expression experiments, the cultures were grown to an optical density (600 nm) of 0.5 in CMdum medium, then supplemented with 2% galactose (w/v) as well as 0.003% of the corresponding fatty acid (w/v; stock solution solubilized in 5% tergitol) and finally grown to saturation for 24 h at 30°C.

Lipid analysis

Lipids were extracted from protonemata and yeast cells by chloroform-methanol extraction (Siebertz *et al.*, 1979) and purified from apolar components by TLC in diethylether. In this solvent all membrane lipids (triacylglycerols were not produced by protonemata) remained at the start. The fatty acid methyl esters (FAME) were obtained by transmethylation of the lipids with 1 N H_2SO_4 in methanol and 2% dimethoxypropane at 80°C for 1 h. The extracted FAME were analysed by gas-liquid chromatography using a capillary column (Chrompack, WCOT Fused Silica, CP-Wax-52 CB, 25 m, 0.32 mm). Their identities were confirmed by comparison with appropriate FAME standards (Sigma). The corresponding fatty acid pyrrolidides were obtained as described elsewhere (Andersson and Holman, 1974) and analysed by GLC-MS on a HP 5989 A instrument (Hewlett-Packard) equipped with an HP-5 column using a temperature gradient 150°C (3 min) → 320°C at 5° min^{-1}. Electron impact (EI) was carried out at 70 eV and chemical ionization mass spectra (CI-MS) were recorded with ammonia as reactant gas (0.1 MPa).

Acknowledgements

This work is based on a doctoral study by Thomas Girke in the Faculty of Biology, University of Hamburg. Support by the Deutsche Forschungsgemeinschaft (He 695/14–1) and the Fonds der Chemischen Industrie is gratefully acknowledged. Ralf Reski is indebted to the Deutsche Forschungsgemeinschaft for a Heisenberg Fellowship (Re 837/3–1). We thank Hermann Moll for skilful help in GC–MS analysis and our colleagues in the EC-funded project EUROMOSS, who shared unpublished results.

Review

Biosynthesis and regulation of linolenic acid in higher plants

Xuemin M. Wang and David F. Hildebrand

Department of Agronomy, University of Kentucky, Lexington, Kentucky, USA.

(Received for publication December 28, 1987; accepted April 14, 1988)

Wang, X.-M. and Hildebrand D. F. 1988. Biosynthesis and regulation of linolenic acid in higher plants. — Plant Physiol. Biochem. 26: 777-792.

The biosynthesis of polyunsaturated fatty acids in higher plants is reviewed with particular emphasis on linolenate biosynthesis. Much information has been gained concerning linolenic acid synthesis by following the fate of radiolabelled precursers *in vivo*. Linolenate synthesis apparently occurs in both the chloroplasts on galactolipids and the endoplasmic reticulum on phospholipids. Linoleate desaturation can be differentially affected by chemical modulators and environmental conditions such as temperature, light and water stress relative to fatty acid biosynthesis resulting in changes in the linolenate content of lipids. Progress on the biochemical characterization of linoleoyl desaturase has been hampered by the apparent instability of the enzyme and the lack of a good *in vitro* assay system. Progress has been made in the breeding of plants for altered seed linolenate content (and other fatty acids) and a number of mutants have been found with altered linolenate levels of seed lipids and some of leaf lipids. Many of these mutants involve only one or two genes and therefore should be very useful in the biochemical and molecular characterization of linolenate biosynthesis in higher plants. The prospects for the genetic engineering of plants for altered fatty acid composition are discussed.

Additional key words — Lipids, fatty acids, polyunsaturated, oils, desaturation.

X.-M. Wang, Department of Botany, Louisiana State University, Baton Rouge, LA 70803 *USA; D. F. Hildebrand (reprint requests), Department of Agronomy, University of Kentucky, Lexington, KY* 40546, *USA.*

Résumé. *La biosynthèse des acides gras polyinsaturés chez les plantes supérieures est passée en revue en insistant spécialement sur la biosynthèse du linolénate. De nombreuses informations ont été obtenues sur la synthèse de l'acide linolénique en suivant* in vivo *le devenir de précurseurs marqués. Apparemment, la synthèse du linolénate a lieu à la fois dans les chloroplastes au niveau des galactolipides et dans le réticulum endoplasmique au niveau des phospholipides. La désaturation du linoléate peut être affectée de différentes manières par des agents chimiques ou des conditions de l'environnement, telles que la température, la lumière, le stress hydrique, qui agissent sur la biosynthèse des acides gras et dont le résultat est une modification du contenu en linolénate des lipides. Les progrès dans la caractérisation biochimique de la désaturase de l'acide linoléique ont été entravés par l'apparente instabilité de l'enzyme et l'absence d'un bon test d'activité* in vitro. *Des progrès ont été faits dans la sélection de plantes dont le contenu des graines en linolénate (et en autres acides gras) a été modifié, et des mutants présentant des teneurs modifiées en linolénate dans les lipides des graines et même des feuilles ont été obtenus. La plupart de ces mutations ne concernent qu'un ou deux gènes; elles devraient.*

donc être très utiles pour la caractérisation biochimique et moléculaire de la biosynthèse du linolénate chez les plantes supérieures. Les perspectives ouvertes pour la production de plantes ayant des compositions en acides gras modifiées sont discutées. Mots clés additionnels : lipides, acides gras, huiles polyinsaturées, désaturation.

Abbreviations. ACP, acyl carrier protein; Ch, choline; CoA, coenzyme A; DAG, diacylglycerol; CDPCh, cytidine diphosphoryl choline; EMS, ethylmethane sulfonate; ER, endoplasmic reticulum; G3P, glycerol 3-phosphate; LPA, lysophosphatidic acid; MGDG, monogalactosyldiacylglycerol; PA, phosphatidic acid; PC, phosphatidylcholine; PLTP, phospholipid transfer protein; TAG, triacylglycerol. C16:0, C18:3, etc., denote number of carbon atoms and double bonds. Pairs of numbers denoting fatty acids and separated by a slash (virgule) for example 18:2/18:3, represent the components at the *sn*-1 and *sn*-2 positions in PC, respectively. *Sn*-1 and *sn*-2 represent the first and second (middle) positions on the glycerol backbone of lipids.

Introduction

Photosynthetic tissues of higher plants typically contain 60-70% of linolenic acid (18:3) which is the most abundant fatty acid in nature (Gounaris and Barber, 1983). The presence of high levels of polyunsaturated fatty acids in plants has been implicated as playing a role in maintaining membrane fluidity of the photosynthetic apparatus and in preventing chilling damage (Raison, 1980; Oquist and Liljenberg, 1981; Harwood, 1983; Quinn and Williams, 1983; Kuiper, 1984).

Linolenic acid is a constituent of seed oil fatty acids in a number of oilseed crops such as soybean, rapeseed, and linseed. The quality of a seed oil is primarily dependent upon its fatty acid composition, which also determines its end use. Soybean oil contains 8% linolenic acid while other oilseed crops such as sesame, cottonseed, and sunflower contain less than 2%. The relatively high 18:3 level in soybean oil is not desirable for its use as a cooking oil due to its inverse correlation with oxidative stability and flavor quality (Smouse, 1979). Commercial soybean oil is a product of refining and industrial hydrogenation of the polyunsaturated fatty acids in the seed oil, which reduces the level of 18:3 and other unsaturated fatty acids. This expensive process also generates isomers of unsaturated fatty acids which are of concern in human health. Therefore, lowering the 18:3 content in soybean seed oil has been endeavored in several laboratories (Howell *et al.*, 1972; Trémolières *et al.*, 1978, 1982; Hammond and Fehr, 1983; Carver and Wilson, 1984; Wilcox *et al.*, 1984). However, progress in the development of commercial cultivars with lower 18:3 content has been slow.

A major factor contributing to the slow progress is the poor understanding of the biosynthesis and regulation of linolenic acid in both leaf and seed tissues (Stumpf, 1980; Frentzen, 1986). The formation of linolenic acid is considered to occur via consecutive desaturations of stearic, oleic, and linoleic acids with each step being catalyzed by a different enzyme (Trémolières and Mazliak, 1974; Cherif *et al.*, 1975; Slack *et al.*, 1978; Roughan *et al.*, 1979 *a;* Stymne and Stobart, 1985). However, little success has been achieved in the attempt to assay linoleoyl desaturase activity *in vitro*, which hampers further isolation and biochemical study of this enzyme. Further, it is not yet fully established which lipids are substrates for desaturation; how many distinct desaturases exist; whether 18:2 to 18:3 conversion occurs outside as well as inside the chloroplast; and how the formation of 18:3 is biochemically and genetically regulated. The present review discusses the current understanding of certain aspects of the biosynthesis and regulation of linolenate in higher plants.

Biosynthesis of polyunsaturated fatty acids

Desaturation of C18 fatty acids

The processes in the synthesis of plant polyunsaturated fatty acids from acetate are well understood up to the step of production of oleic acid (*fig.* 1). Enzymes involved in the formation of saturated fatty acids as far as stearic acid are all soluble, residing in the stromal phase of plastids (Stumpf, 1980).

The synthesis of oleic, linoleic, and linolenic acids in higher plants is thought to occur through consecutive desaturations from stearic acid (Roughan *et al.*, 1979 *a;* Jaworski, 1987). The first step of desaturation from stearate to oleate is catalyzed by stearoyl-ACP desaturase (Nagai and Bloch, 1968) and occurs in the stromal phase of chloroplasts. Unlike all other known desaturases, this desaturase is soluble instead of membrane bound and was the first plant desaturase to be studied in great detail in plants (Gurr, 1974). This enzyme uses stearoyl-ACP as the substrate and yields oleoyl-ACP as the product (Stumpf and Porra, 1976; Ohlrogge *et al.*, 1978). The reaction requires an NADH ferredoxin reductase, ferredoxin, as well as the desaturase; and

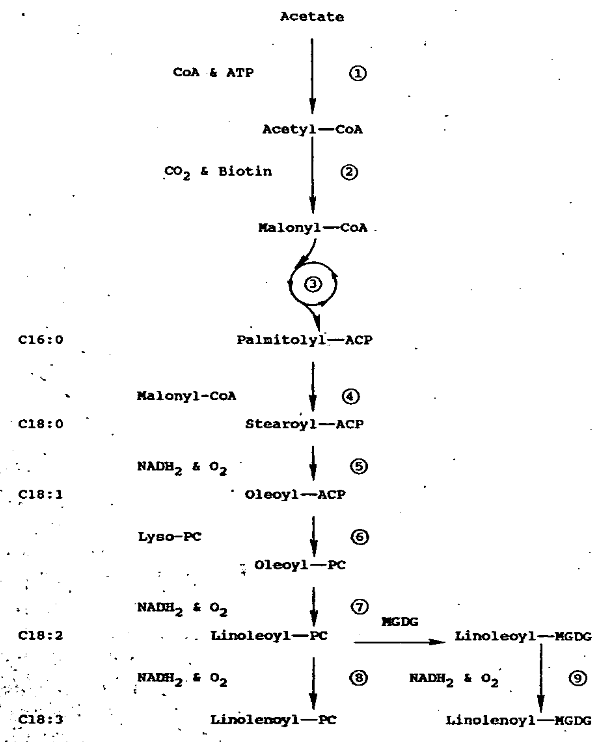

Figure 1. *A scheme showing the biosynthetic pathway of polyunsaturated fatty acids according to the references given in text.* The enzymes catalyzing individual reactions are: (*1*), acetyl-CoA synthetase; (*2*), acetyl-CoA carboxylase; (*3*), fatty acid synthetase; (*4*), fatty acid elongase; (*5*), C18:0 desaturase; (*6*), lysophosphatidylcholinetransferase; (*7*), C18:1 desaturase; (*8*) and (*9*), C18:2 desaturase(s).

can be inhibited by cyanide (Nagai and Bloch, 1968; Jaworski and Stumpf, 1974). In plants, ferredoxin acts as an intermediate electron carrier, transporting two electrons from NADH or water to the double bond being acted on by the desaturase.

Stearoyl-ACP desaturase has been isolated and purified from developing safflower seeds. It was found to be a dimer with a molecular mass of 68 kDa, it required 400 µM oxygen for maximal activity and was stimulated several fold by catalase (McKeon and Stumpf, 1982). In developing seeds as in leaves, the desaturation of stearic acid to oleic acid apparently occurs in plastids (Stumpf, 1980).

The elucidation of the biosynthesis of two polyunsaturated fatty acids, namely linoleate and linolenate, is based mostly on intact tissue investigation or experiments with membrane fractions such as microsomes. Attempts to obtain systems which can be purified and thereby fully characterized have been unsuccessful, but desaturation of oleic to linoleic acids likely occurs outside the chloroplast in both photosynthetic and non-photosynthetic tissues (Roughan and Slack, 1982). Studies have demonstrated that intact chloroplasts only synthesize oleic acid, although small amounts of linoleic and linolenic synthesis have been noted (Heinz *et al.*, 1979). The resulting oleic acid in chloroplasts is transferred to the cytoplasm and esterified to phosphatidylcholine (PC), which acts as the substrate for the desaturation to linoleic acid. The oleoyl-PC desaturase is membrane bound and localized in the endoplasmic reticulum (ER) (Abdelkader *et al.*, 1973; Dubacq *et al.*, 1976; Slack *et al.*, 1976; Trémolières *et al.*, 1980 *a*). It requires NADH and O_2 for activity and it is inhibited by cyanide (Stymne and Appelquist, 1978). In developing seeds, the activity of this enzyme is relatively easily measured in crude cell-free homogenates and microsomal fractions (Stymne and Appelquist, 1980). The desaturation of oleoyl-PC in isolated microsomes from young pea leaves was found to occur predominantly on the *sn*-2 position of PC (Murphy *et al.*, 1985); whereas, the desaturation of oleoyl-PC in isolated potato tuber microsomes was found to occur on both positions although again mostly on the *sn*-2 position (Demandre *et al.*, 1986). However, the isolation and purification of this enzyme has not yet been achieved.

Information concerning the desaturation of linoleate to linolenate is currently very limited. The microsomal desaturation product, linoleoyl PC, is transferred back to the chloroplast. A purified PLTP has been demonstrated as being capable of carrying phospholipids from microsomes to intact chloroplasts (Trémolières *et al.*, 1980 *b*; Drapier *et al.*, 1982; Ohnishi and Yamada, 1982; Dubacq *et al.*, 1984; Grechkin *et al.*, 1984). There has been considerable discussion as to whether the substrates of linoleoyl desaturase are phospholipids, fatty acid CoA forms, or galactolipids (Stumpf, 1980; Roughan and Slack, 1982). In plant leaf tissues, both galactolipids and phospholipids are thought to serve as the substrates (Roughan and Slack, 1984; Williams *et al.*, 1983); while in developing seeds, phosphatidylcholine is believed to be the substrate (Slack *et al.*, 1979). Linoleoyl desaturase resembles other known desaturases in that NADH and O_2 are required for activity and its activity is inhibited by cyanide. This enzyme is considered to reside in chloroplasts in leaf tissues. The activity of a linoleoyl desaturase has been demonstrated to occur in thylakoids of pea chloroplasts (Grechkin *et al.*, 1984). However evidence for more than one site for the formation of 18:3 in plant cells has been accumulating (Frentzen, 1986).

Though plants accumulate large amounts of linolenic acid, the activity of linoleoyl desaturase is very low and less stable relative to other desaturases. Few reports have dealt with the *in vitro* assay of linoleoyl desaturase activity. The activity of linoleoyl desaturase can be assayed by feeding [^{14}C]linoleic acid to intact plants or homogenates. Catalase stimulates the activity of this enzyme (Browse and Slack, 1981). Differential centrifugation of soybean homogenates caused a complete loss of its activity (Stymne and Appelquist, 1980), but the enzyme from linseed cotyledons has been partially stabilized and shown to be located in microsomes (Browse and Slack, 1981). Attempts to further isolate the enzyme have not been successful.

Procaryotic and eucaryotic pathways for the formation of polyunsatured fatty acids

Two different pathways for the formation of lipids in higher plants have been proposed (Roughan *et al.*, 1980; Heinz and Roughan, 1982; Gounaris *et al.*, 1986; Heemskerk *et al.*, 1987). The characteristics of the two pathways are originally based on the positionally specific distributions of the fatty acids between the two positions of the glycerol backbone (Heinz, 1977). In the procaryotic (intraplastidic) pathway, galactolipid synthesis begins with the assembly of predominantly 18 carbon fatty acids on glycerol-3-P forming lysophosphatidic acid followed by incorporation of 16 carbon fatty acids at the *sn*-2 position forming 1-18-2-16-phosphatidic acid (PA) (Sauer and Heise, 1982). The PA is cleaved by a phosphatase, yielding diacylglycerol which is subsequently galactosylated to form MGDG (Frentzen *et al.*, 1982). This group of lipids is exclusively esterified with C16 fatty acids at the *sn*-2 position, while the *sn*-1 position contains C18- and to a lesser extent C16-acyl groups. Since this distribution corresponds to the typical fatty acid pattern of glycerolipids from cyanobacteria, it is called the procaryotic pathway. This pathway is located in chloroplasts and uses galactolipid intermediates as precursors (Roughan and Slack, 1982). The other system is the eucaryotic pathway which forms glycerolipids having C18-fatty acids at both positions. C16-acyl groups are excluded from the *sn*-2 position of lipids formed by the eucaryotic pathway (Williams *et al.*, 1983). This eucaryotic pattern is characteristic of glycerolipids from extraplastidic membranes. Subsequent evidence indicates that the eucaryotic pathway occurs in the cytosol phase and involves microsomal PC as the substrate (Frentzen, 1986).

The basis of the two pathway hypothesis is that fatty acids synthesized *de novo* in the chloroplast may either be used directly for production of chloroplast lipids via the procaryotic pathway (Roughan *et al.*, 1980; Sparace and Mudd, 1982; Heinz and Roughan, 1983), or be exported to enter the eucaryotic pathway at an extrachloroplastic site, particularly in the endoplasmic reticulum (Block *et al.*, 1983; Dubacq *et al.*, 1983; Oursel *et al.*, 1987). The diacylglycerol moiety of PC synthesized by the eucaryotic pathway is returned to the chloroplast probably by the action of a PLTP, where it contributes to the production of thylakoid lipids (Ohnishi and Yamada, 1982; Dubacq *et al.*, 1984). In the eucaryotic pathway, molecular species of PC produced in the microsomes, composed mainly of 18:2 and 18:3 at both the *sn*-1 and *sn*-2 positions, serve as a precursor of MGDG synthesis in the chloroplast (Norman and St. John, 1986).

These two different pathways for the synthesis of plant lipids have been suggested to be associated with the production of polyunsatured fatty acids. This theory is based on the accumulating data from [^{14}C]acetate, $^{14}CO_2$, [^{3}H]glycerol and [^{14}C]oleate labelling of leaves and algae cells *in vivo* (Appleby *et al.*, 1971; Williams and Khan, 1982); from labelling experiments with isolated chloroplasts and microsomal fractions *in vitro* (Roughan *et al.*, 1980; Dubacq *et al.*, 1983); and from enzymological studies (Joyard and Douce, 1977; Douce and Joyard, 1979; Block *et al.*, 1983; Frentzen *et al.*, 1983, 1984). In the procaryotic pathway, 18:1/16:0 monogalactosyl diacylglycerol (MGDG) is synthesized within chloroplasts and desaturated *in situ* to form 18:3/16:3 MGDG (Siebertz *et al.*, 1980). An eucaryotic pathway involving desaturation of microsomal PC provides the diacylglycerol (DAG) precursors for 18:3/18:3 MGDG synthesis (Roughan and Slack, 1984). For example, in *Arabidopsis thaliana*, 18:2/16:2 MGDG (procaryotic pathway) is the substrate for production of 18:3 at the *sn*-1 position of MGDG. The desaturation of 18:2 on PC (eucaryotic pathway) provides 18:2/18:3 PC as a precursor for 18:3/18:3 MGDG synthesis (Norman and St. John, 1986).

According to the positional and fatty acid specificities of the glycerophosphate and monoacylglycerolphosphate acyltransferase, phosphatic acids with a procaryotic pattern are formed in the chloroplast envelope (Stobart *et al.*, 1983; Stymne and Stobard, 1984*a* and *b*, 1985). This phosphatic acid serves as the substrate for the subsequent biosynthesis of monogalactosyldiacylglycerol as well as phosphatidylglycerol. The ability to form procaryotic glycerolipid is decisively controlled by the activity of the plastidial phosphatidic acid phosphatase (Gardiner *et al.*, 1982; Heinz and Roughan, 1983). *In vitro* labelling experiments with isolated chloroplasts from different 16:3 and 18:3 plants indicate that the phosphatase activity is highly correlated with the

amount of 16:3. In the 16:3-plant spinach, this phosphatase is located in the outer membrane of the chloroplast (Joyard and Douce, 1977).

The ER is the primary site of the biosynthesis of eucaryotic glycerolipids in the extraplastidic part of the cell (Moore, 1982; Sauer and Robinson, 1985). The activities of the ER are relevant to the biogenesis of the cells' entire membrane system. However, the microsomal system from photosynthetically active tissues is less well characterized than that from developing seeds. PC has a decisive metabolic role not only in the biosynthesis of eucaryotic diacylglycerolipids in leaves, but also in the biosynthesis of polyunsaturated TAGs in developing seeds (Slack *et al.*, 1978; Roughan and Slack, 1984). The phosphatidic acid formed in the ER membrane serves as a precursor for the biosynthesis of the different phospholipids which can subsequently be used for linoleic and linolenic acid biosynthesis. The desaturation of acyl groups in the ER is conclusively demonstrated to occur on those esterified to PC (Roughan and Slack, 1984). This desaturation occurs in membrane fractions not only from developing oilseeds, but also from photosynthetic tissues.

The relative contribution of these two pathways to MGDG synthesis establishes the fatty acid composition in a given plant species (Roughan, 1985). For example, if only the eucaryotic pathway is used, the plant is classified as an "18:3" species. If the procaryotic pathway contributes substantially to cellular lipids, the plant is termed a "16:3" species. A wide variation in the percentage of 16:3 in MGDG has been observed among plant species (Jamieson and Reid, 1971) and this diversity is considered to reflect the relative activity of enzymes involved in the two separate biosynthetic pathways (Roughan, 1975).

The glycerolipid biosynthesis capacity in the two pathways must be well balanced to result in the different levels of procaryotic and eucaryotic glycerolipids in the membrane system of chloroplasts of various plants (Douce and Joyard, 1979). In *A. thaliana*, almost equal amounts of chloroplast lipids are synthesized by the procaryotic and eucaryotic pathways (Browse *et al.*, 1986*b*). The quantities of individual lipids produced by the two routes are very different. Chloroplast phosphatidylglycerol is synthesized via the procaryotic pathway, whereas chloroplast PC is a product of the eucaryotic pathway. In one *A. thaliana* mutant (JB1), the synthesis of 18:3 from the procaryotic pathway is deficient, but plants compensate by producing more 18:3 from the eucaryotic pathway (Norman and St. John. 1986).

The production of glycerolipids in the two biosynthetic pathways is also modulated by the concentrations of glycerol 3-phosphate (Gardiner *et al.*, 1982). This regulation probably results from the differing affinities of the glycerol 3-phosphate acyltransferase for the acyl acceptor. Results of *in vivo* and *in vitro* labelling experiments showed that an increased cellular concentration of glycerol 3-phosphate in leaves of 16:3 and 18:3-plants had no effect on the total incorporation of acetate into lipids, but significantly stimulated the synthesis of procaryotic glycerolipids (Gardiner *et al.*, 1982).

Synthesis of polyunsaturated fatty acids in seed triacylglycerols

The fatty acid composition of TAGs in oilseeds is species and often variety specific (Hilditch and Williams, 1964; Downey and McGregor, 1975). The relative proportions of the constituent fatty acids esterified at the three positions of the glycerol molecule also differ considerably. In general, the unsaturated C18 fatty acids, oleic, linoleic, and linolenic acids are major constituents of the TAGs of edible oilseed crops.

PC plays an important metabolic role during the formation of polyunsaturated triacylglycerols in seeds (Wilson *et al.*, 1980). In developing cotyledons, labelled fatty acids accumulate rapidly into PC and diacylglycerols, but initially only at a slow rate into TAG. During a chase, following pulse-labelling, radioactivity is lost largely from the oleic acid of this phospholipid and accumulates in the polyunsatured C18 fatty acids, linoleate and linolenate of triacylglycerols (Dybing and Craig, 1970; Slack *et al.*, 1978). *In vitro* the microsomal desaturase from developing cotyledons uses oleoyl and linoleoyl PC as substrates to form linoleoyl and linolenoyl PC, respectively, as products (Stymne and Appelquist, 1978; Slack *et al.*, 1979; Browse and Slack, 1981). Consequently, this phospholipid appears to serve as a donor of these fatty acid for TAG formation (*fig.* 2). Other phospholipids, in addition to PC, can also serve as acyl donors (Wilson *et al.*, 1980). Since labelled glycerol moieties as well as acyl moieties were transferred from PC to TAG during a chase, it is suggested that this phospholipid could provide both the DAG and the fatty acids from which TAG is formed (Slack *et al.*, 1978).

The microsomal fraction from oilseeds possesses all the necessary enzyme activities for *de novo* biosynthesis of TAGs, namely glycerol 3-phosphate acyltransferase, monoacylglycerol 3-phosphate acyltransferase, phosphatidic acid phosphatase and diacylglycerol acyltransferase (*fig.* 2). PC formed in the microsome is used as a substrate for the subsequent desaturation of the oleoyl groups esterified at the *sn*-1 as well as the *sn*-2 position of the glycerol

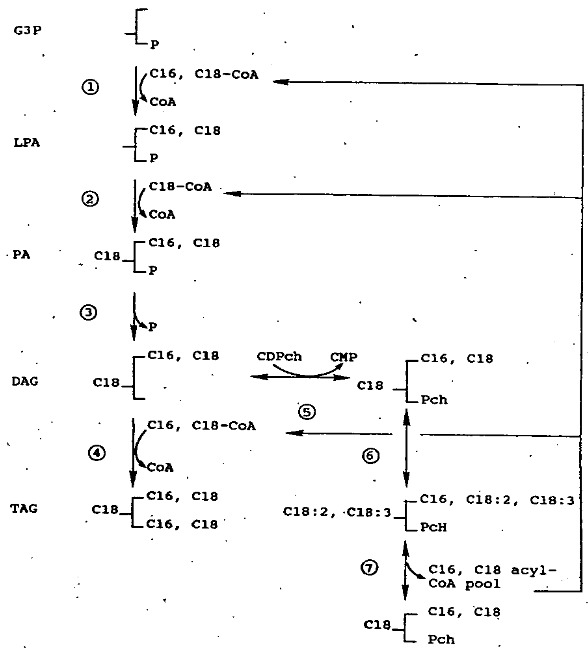

Figure 2. *A scheme showing the biosynthetic pathway of polyunsaturated triacylglycerols in developing oilseeds according to the references given in text.* C16 is mostly C16:0 whereas C18 can be C18:0, C18:1, C18:2, or C18:3. The enzymes catalyzing individual reactions are: (*1*), G3P acyltransferase; (*2*), 1-acylglycerol 3-P acyltransferase; (*3*), PA phosphatase; (*4*), DAG acyltransferase; (*5*), DAG choline phosphotransferase; (*6*) C18:1 and C18:2 PC desaturases and (*7*), lyso-PC acyltransferase.

backbone (Slack *et al.*, 1979; Rochester and Bishop, 1984; Stobart and Stymne, 1985). The lysophosphatidylcholine acyltransferase in the microsomal fraction exclusively attacks the *sn*-2 position of PC. It possesses a high specificity for unsaturated C18-fatty acids and a slight preference for C18:1 (Stobart *et al.*, 1983; Stymne *et al.*, 1983). Hence this enzyme preserves the eucaryotic fatty acid pattern but affects an acyl exchange between acyl-CoA and position 2 of PC by the combined backward and forward reactions. The biosynthetic pathway making polyunsaturated fatty acids of TAGs via PC can be channeled to TAGs by the reverse reaction of cholinephosphotransferase. These combined forward and backward reactions alter the acyl-CoA mixture exported from the plastids, resulting in a decrease of C18:1 and an increase of C18:2 or C18:3 groups corresponding to the fatty acid sensitivity of the acyltransferase and the fatty acid composition at position 2 of PC, respectively. The acyl exchange coupled to the DAG PC equilibrium gives rise to a continued enrichment of the glycerol backbone with polyunsaturated fatty acids (Griffiths *et al.*, 1985; Stobart and Stymne, 1985; Stymne and Stobart, 1985). By this pathway the whole DAG moiety of PC is incorporated into TAGs (Stymne and Stobart, 1984 *b*).

In maturing soybean seeds, the formation of linolenate is developmentally regulated. The amount of linolenic acid is highest during the very early stages of seed formation with the relative amount decreasing at the later stages of development (Reubel *et al.*, 1972; Roehm and Privette, 1970; Cherry *et al.*, 1984). Assays of cell-free extracts have demonstrated that the homogenates of early stage cotyledons possess higher and more stable linoleoyl desaturase activity than those of later stages (Stymne and Appelquist, 1980).

Manipulation of the synthesis of polyunsaturated fatty acids

Genetic alteration of the synthesis of polyunsaturated fatty acids

Substantial variation occurs among species in the level of polyunsaturated fatty acids in seed oil. Some species, such as sunflower (*Helianthus annus*) and safflower (*Carthamus tinctorius*) contain essentially no linolenic acid, but have high levels of linoleic acid. However others, including soybean (*Glycine max*) rapeseed/canola (*Brassica napus* and *B. campestris*) and flax (*Linum usitatissimum*), all contain significant quantities of linolenic acid (Downey, 1987). The content and composition of polyunsaturated fatty acids in lipids is genetically regulated in plants. The genetic control of polyunsaturated fatty acid synthesis is best studied by isolation and characterization of mutants with altered formation of these fatty acids. Such mutants have been isolated from various plant species by means of physical and chemical mutagenesis. Among these are mutants from *A. thaliana* (Browse *et al.*, 1986 *a*), flax (Green and Marshall, 1984; Green, 1986), soybeans (Wilson *et al.*, 1981; Hammond and Fehr, 1983; Wilcox, *et al.*, 1984), and *Brassica* oilseed crops (Rakow, 1973; Robbelen and Nitsch, 1975) which have been studied in some detail.

The *A. thaliana* fatty acid desaturation mutants isolated and characterized by Browse, Somerville and coworkers (Browse *et al.*, 1984, 1985, 1986 *a*; Somerville *et al.*, 1987) have particular promise in facilitating the elucidation of the molecular genetic controls and functional significance of unsaturated fatty acids in plant leaves. Four mutants (designated *fadA*, *fadB*, *fadC* and *fadD*) isolated by direct analysis of fatty acid composition of leaf tissues from

an ethylmethane sulfonate (EMS)-mutagenized population of plants (Browse *et al.*, 1986 *a*) have been tentatively described in terms of the sites of the particular enzymatic lesions (Somerville *et al.*, 1987). The *fadA* mutants apparently lack the desaturase which converts 16:0 to *trans*-3-hexadecenoic acid. The *fadB* mutants accumulate high levels of 16:0 but are deficient in 16:1, 16:2 and 16:3 fatty acids. The wildtype and the mutants *fadC* and *fadD* contain almost identical C16/C18 ratios. However, the fatty acid composition of *fadD* shows a decreased level of both C18:3 and C16:3 with a corresponding increase of C18:2 and C16:2 in comparison to the wildtype. The mutant *fadC* also contains reduced levels of polyenoic acids, but in this mutant it is the monoenoic acids which show a corresponding increase. These results imply that the desaturase activities affected by the mutations in *fadC* and *fadD* can act on both C16 and C18 acyl groups, and the site for the insertion of a new double bond is determined from the methyl end of the chain. In chloroplasts, the biosynthesis of dienoic and trienoic acids is therefore catalyzed by *n*-6 and *n*-3 desaturase activities (Frentzen, 1986).

The kinetics of in vivo labelling of lipids with [^{14}C]acetate and quantitative analysis of the fatty acid composition of individual lipids suggest that reduced activity of a glycerolipid *n*-3 desaturase is responsible for the altered lipid composition of the *fadD* mutant (Browse *et al.*, 1986 *a* and *b*). The effects of the mutation are fully expressed when plants are grown at temperatures above 26°C, but are relatively minor below 18°C, suggesting a temperature sensitive enzyme. Both chloroplast (16:3 containing) and extrachloroplast (18:3 in extrachloroplast membranes) lipids are equally affected by the mutation, indicating that either the desaturase is located both outside and inside the chloroplast or C18:3 formed inside the chloroplast is re-exported to other cellular sites.

Studies on the synthesis of unsaturated MGDG molecular species of the *fadD* mutant suggest that multiple substrates are involved in the desaturation of linoleic acid to linolenic acid for the production of unsaturated galactolipids (Norman and St. John, 1986). The mutation selectively reduces the levels of 18:3/16:3 and increases the amount of 18:3/18:3 despite the overall reduction in 18:3, suggesting that a chloroplastic pathway for desaturation at the *sn*-1 position of MGDG utilizes 18:2/16:2 MGDG as the substrate. This procaryotic pathway is apparently deficient in this mutant. The eucaryotic pathway desaturating 18:2 to 18:3 at the *sn*-2 position of PC predominates in the mutant. Genetic characterization of the *fadD* mutation showed that the low trienoic fatty acid content is controlled by a single recessive nuclear gene. There is no change in the fatty acid composition of seed and root lipids in this mutant (Browse *et al.*, 1986 *a*), indicating that different pathways or isozymes may operate in the different tissues.

The nutritional and industrial value of seed storage lipids is dependent primarily upon the fatty acid composition. Of particular importance is the relative proportion of the C18 unsaturated fatty acids namely oleic, linoleic and linoleic acids (Smouse, 1979). Oils with high levels of polyunsaturated fatty acids particularly linolenic acid are less suitable for use as cooking oils due to the poor oxidative stability of these fatty acids. Efforts have therefore been expended on altering the fatty acid composition of seed storage lipids to meet the desired end use of the oils [it should be noted however, that 18:3 (an omega-3 fatty acid) has recently been implicated as playing an important role in human health (Booyens and van der Merwe, 1985)].

Searching for and using genetic variants of fatty acid composition have become common approaches to achieving the manipulation of fatty acid composition in seed oil crops. For example, flax oil contains a high percentage of 18:3 fatty acid (45%-65%). This high level precludes its use as an edible oil and gives its traditional industrial use. Genotypes with 2% 18:3 have been isolated (Green, 1986). This alteration is achieved by selection within the F2 generation of a cross between two induced mutants with reduced levels of linolenic acid (28%-30%) (Green and Marshall, 1984). This near elimination of linolenic acid from the seed lipids is accompanied by a comparative increase in the content of linoleate, with the proportions of other fatty acids remaining unaltered. These results indicate that the mutations block the final desaturation of linoleic to linolenic acid. Genetic analysis of crosses among these mutants and their parental cultivar revealed that these mutations are in different unlinked genes and exhibit additive (codominant) gene action. Two genetic loci with additive effects have therefore been identified to control the linolenate content (Green, 1986).

Soybean seed oil is the most common edible oil in the world (Smith, 1981). About eight percent is composed of 18:3 and this relatively high content of linolenic acid as well as linoleic acid has been considered to be an important factor lowering the autooxidative and flavor stability of soybean oil. Accessions of the commercial soybean species (*Glycine max.*) display 18:3 content of 4-15% of the seed oil. In other species of the genus *Glycine*, the linolenate content ranged from 11.3-27.2% (Smith, 1981; Chaven *et al.*, 1982). The lack of genotypes with very low 18:3 content within the genus *Glycine* has spurred other approaches to reduce the 18:3 content in soybean seed oil.

Thus far, the most effective approach to develop soybean strains with genetically determined low levels of linolenic acid has been the use of chemical mutagens. Treatment with EMS significantly increased the variation in the fatty acid composition in the soybean cultivar "Century". A genetically stable mutant designated C1640 with 3.4% 18:3 was identified (Wilcox *et al.*, 1984). This mutation is controlled by a single gene locus (Wilcox and Cavins, 1985) designated *Fan* (Wilcox and Cavins, 1987). Treatment of one low linolenic acid breeding line after recurrent selection with EMS resulted in a line, designated A5, with linolenic acid content of 2.9-4.1% (Hammond and Fehr, 1983, 1984). Graef *et al.* (1988) demonstrated that fatty acid composition should be considered a quantitative character in crosses which involve A5 as a parent. The decreased 18:3 content in A5 is apparently the result of a decreased rate of 18:1 desaturation of oleoyl-PC in this genotype. Interestingly we find that both C1640 and A5 have reduced 18:3 in root lipids but not in any other vegetative tissues (Wang *et al.*, 1988). A5 had a corresponding increase in 18:2 in the root lipids in contrast to the increase in 18:1 in the seed lipids (Wang *et al.*, 1988).

Recurrent selection for high oleic acid and a high ratio of 18:1 to 18:2 + 18:3 has been conducted to alter the fatty acid composition of soybean oil (Wilson *et al.*, 1981). The results of this study showed that the 18:1 content of the oil increased linearly from 24.8 to 33.0%. The inversely correlated trait, 18:3, was reduced linearly from 7.8 to 6.3%.

An objective of rapeseed (8-10% 18:3) breeding has been to reduce the level of linolenic acid to less than 3% while maintaining or increasing the level of the nutritionally desirable linoleic acid presently at 20-25%. [It should be noted, however, that the major objective of the genetic improvement of rapeseed oil has been to reduce the erucic acid content (22:1). Breeding efforts toward these goals have been highly successful resulting in the development, for instance, of the new Canola type rapeseed oil with a reduction of erucic acid from about 50% to less than 1% and a corresponding increase in oleic acid (18:1) (Downey, 1987). The canola oils are acceptable for many edible purposes even though they have an 18:3 content averaging 10% because of the high 18:1/18:2 + 18:3 ratio.] Chemical mutagenesis was successful in reducing the linolenic acid level to 5.5% (Rakow, 1973) and subsequent selection produced material with a linolenate level as low as 3.2% (Robbelen and Nitch, 1975). In the *Brassica* species, linolenic acid biosynthesis was observed to occur only in those seeds which possess green photosynthetically active chloroplasts during certain stages of their development (Thies, 1970).

Studies of the metabolism of MGDG molecular species in *A. thaliana* leaf mutants have revealed different sites and substrates for linolenic acid synthesis (Norman and St. John, 1986). The use of other mutants with low seed 18:3 for elucidating the mechanism of regulation and synthesis of linolenate is however still at preliminary stages. Despite great efforts having been expended on the selection of low 18:3 mutants in soybeans, no 18:3-null mutants have been found. It is not yet clear if a certain amount of 18:3 is essential for soybean seed development. However, the near absence of 18:3 in other oilseed crops diminishes this possibility. Inconsistent expression of the low 18:3 trait in various tissues has been observed in soybean seed mutants (Martin and Rinne, 1985). The reduction of linolenate content in some mutants is due to the blockage of desaturation at 18:1, whereas others occur at the 18:2 desaturation step (Cherry *et al.*, 1984). Nevertheless, these mutants have provided an instrumental approach to the study of 18:3 biosynthesis and regulation.

Chemical modulation of the formation of polyunsaturared fatty acids

One substituted pyridazinone, San 9785 (4-chloro-5-dimethylamino-2-phenyl-3(2H) pyridazinone), is a potent inhibitor of the desaturation of linoleate to linolenate (St. John, 1976; Lem and Williams, 1981). San 9785 has been shown to selectively affect the levels of linolenate in several species of higher plants without causing any gross change in leaf development and chloroplast content (Laskay *et al.*, 1983). Labelling studies with fatty acid precursors, such as $^{14}CO_2$ and [^{14}C]acetate, have demonstrated a reduction in linolenate radiolabelling in the presence of San 9785 and a concomittant increase in the levels of [^{14}C]linoleate (Willemot *et al.*, 1982). Therefore, San 9785 has been considered to have a direct effect upon the conversion of linoleate to linolenate. This compound has been widely used in the manipulation and study of the synthesis and function of linolenic acid.

It is suggested that San 9785 inhibits 18:3 formation at the procaryotic pathway with little effect on the eucaryotic one (Lem and Williams, 1981; Norman and St. John, 1987). San 9785 was shown to reduce linoleate desaturation of MGDG but not PC. The differential effects of San 9785 on the pathway of MGDG synthesis was studied in *A. thaliana* (Norman and St. John, 1987). 18:3/16:3 MGDG was decreased by San 9785, and 18:2/16:3 and 18:2/16:2 MGDG concurrently increased. Kinetic studies using exogenously incorporated [^{14}C]18:1 indicated that

18:3/18:3 MGDG originated from a 18:2/18:3 diacylglycerol precursor derived from PC. The formation of 18:3 at the *sn*-2 position of PC was less sensitive to San 9785 than desaturation of 18:2 at the *sn*-1 position of 18:2/18:3 MGDG which is proposed to occur within the chloroplasts.

Direct evidence has shown that the site of action of San 9785 on fatty acid biosynthesis in higher plants is at the level of linoleic acid desaturation, but there are large variations in sensitivity between plant species (Hilton *et al.*, 1971; Murphy *et al.*, 1980, 1985). Effects of San 9785 have also been reported upon photosynthetic oxygen evolution (Khan *et al.*, 1979 *a;* Lem and Williams, 1981), thylakoid ultrastructure and chlorophyll-proteins (Khan *et al.*, 1979 *b;* Davies and Harwood, 1983; Leech and Walton, 1983). It has been reported that, whereas San 9785 inhibits the incorporation of [^{14}C]acetate into linolenate in spinach leaf discs, it had no effect upon this incorporation in either isolated chloroplasts or whole leaves of spinach (Willemot *et al.*, 1982). The effects of San 9785 upon photosynthetic oxygen evolution that were reported from both *Vicia faba* leaf discs and isolated spinach chloroplasts were not found in the case of whole leaves of barley. It therefore appears that San 9785 may be quite variable in its effects upon plants depending on the species studied and the pretreatment of the tissues.

Uptake studies demonstrated that the uptake of San 9785 was a reflection of water uptake (Murphy *et al.*, 1985). Following its uptake, San 9785 was rapidly converted into other compounds in pea, but only gradually metabolized in cucumber and ryegrass. The differential sensitivity of higher plants to San 9785 was shown to be due to variation both in uptake and in metabolism.

San 9785 reduces the 18:3 content in soybean cotyledons developing *in vitro* (St. John *et al.*, 1984; Wang *et al.*, 1987 *a*). It also decreases the activity of lipoxygenase, an enzyme catalyzing the oxidation of polyunsaturated fatty acids, in peanut and soybean seeds (Ory *et al.*, 1981, 1984; St. John *et al.*, 1984; Wang and Hildebrand, 1987). Treatment with San 9785 causes these changes without affecting the yield and other important agronomic parameters. Thus, it is suggested that this compound could be applied to the improvement of soybean quality.

The mode of action of San 9785 on the inhibition of linoleate desaturation is not currently understood. The observation that San 9785 had little effect on linolenate synthesis in isolated chloroplasts (Willemot *et al.*, 1982) suggests that either protein synthesis is required for San 9785 action or it needs to be metabolized first in the cytosol in order to be functional. In addition, the decrease of radioactive labelling of linolenate in treated tissues is often seen after prolonged incubation with San 9785 (Lem and Williams, 1981; Davies and Harwood, 1983). This delay may be due do the slow uptake of San 9785; to a delay in the conversion to active metabolites (St. John and Hilton, 1976); to an inhibition of the synthesis of linoleate desaturase; and/or to an elevation of degradation of the desaturase by this compound. Furthermore, the inhibition of linoleate desaturation by San 9785 does not occur in the presence of cycloheximide (Norman, personal communication), a cytosol protein synthesis inhibitor, indicating that protein synthesis is required for San 9785 function.

Environmental effects on the synthesis of polyunsaturated fatty acids

The synthesis of linolenic acid in plants can be affected by a number of environmental factors which include temperature, light, water stress and salt stress (Harwood, 1984; Trémolières, 1985). Low temperature often stimulates the synthesis of polyunsaturated fatty acids in various plant tissues (Hazel and Prosser, 1974). Plants grown at low temperatures during seed maturation accumulate more 18:3 in TAGs than those grown at high temperatures (Reubel *et al.*, 1972; Hawkins *et al.*, 1983 *a* and *b;* Cherry *et al.*, 1985). A change in the ambient temperature caused a marked alteration over a 24 h period in the proportions of unsaturated C18 fatty acids in PC and DAG during soybean and linseed cotyledon development (Slack and Roughan, 1978). At high temperatures, 18:1 increased and 18:2 and 18:3 decreased. For soybean cultivars with different levels of linolenate grown in Northern areas (low temperature) and Southern areas (high temperature), seeds produced in the North are significantly higher in myristate and linolenate, but are lower in oleate (Cherry *et al.*, 1985). Trémolières *et al.* (1978, 1982) found that in rapeseed low temperatures increased the level of polyunsaturated fatty acids at the expense of oleic acid biosynthesis without change of the total lipid content. Similar effects of temperature on polyunsaturated fatty acid synthesis have also been observed in plant cells in culture (Trémolières *et al.*, 1978; MacCarthy and Stumpf, 1980; Trémolières *et al.*, 1982). However, in developing sunflower seeds (Trémolières *et al.*, 1982) low temperatures decreased lipid accumulation with little change in fatty acid composition. Linolenic acid biosynthesis in *Pharbitis nil* cotyledons was likewise very slow at lower temperatures (17C) compared to higher temperature (27C).

There is some controversy concerning the reason for the elevated lipid desaturation in plants grown

at low temperatures. Three schools of thought exist. Some believe that low growth temperature results in an alteration of the activity or amounts of the desaturase enzymes themselves and that such changes are adaptive, enabling cellular membranes to function more effectively (Thompson, 1980). Others propose that the low growth temperature increases oxygen solubility, therefore providing more substrate for the existing desaturase enzymes (Rebeillé *et al.*, 1980). Still others (Browse and Slack, 1983) found evidence which suggests that the apparent increased lipid desaturation at lower temperature in developing safflower cotyledons is actually the consequence of greater increases in fatty acid synthesis than oleate desaturation at higher temperatures which therefore decreases the ratio of polyunsaturated to monounsaturated fatty acids at higher temperatures.

Light also has a profound impact on linolenic acid synthesis. Linolenic acid, esterified to phospholipids or galactolipids, is the principal component of the lipid matrix of photosynthetic membranes of chloroplasts (James and Nichols, 1966), and it can account for up to 90% of the total fatty acids in that organelle (Leech and Murphy, 1976; Trémolières, 1985). The easiest and most widely used experimental system is the greening of etiolated tissues. Etioplasts contain much lower levels of linolenate than chloroplasts (Trémolières and Lepage, 1971; Nichols, 1965; Trémolières and Mazliak, 1970). Darkgrown pea seedlings are rich in linoleic acid. After illumination of these seedlings, a very significant increase in linolenic acid is observed in the young leaf sections, whereas only small variations are seen in fatty acid composition of other sections (Trémolières and Lepage, 1971). Studies have also shown that photoautotrophic cells in culture produce much more linolenic acid than heterotrophic cells (Husemann *et al.*, 1980).

It was found that greening cucumber cotyledons exhibited a dramatic increase in the ability to desaturate exogenously added [^{14}C]linoleic acid (Murphy and Stumpf, 1979). The inhibition of the light-dependent increase in desaturating activity by cycloheximide suggests that this process is dependent on protein synthesis on the 80S ribosomes (*i.e.* cytoplasmic), which parallels similar findings in other light-induced systems. However, oleate and linoleate desaturation in leaves of maize seedlings was largely independent of the previous light treatment of the seedlings (Hawke and Stumpf, 1980); there was no evidence of light-induced desaturase activities. These results are in sharp contrast to those observed with developing cucumber cotyledons. *In vivo* desaturase activity was present in tissues of widely different levels of differentiation and chlorophyll content obtained from light grown maize seedlings.

Water stress on plants likewise results in a change of linolenic acid synthesis (Pham-Thi *et al.*, 1982). Drought appears to reduce the ability of plants to synthesize 18:3. Studies have shown a decrease in this polyunsaturated fatty acid in cotton leaves submitted to water stress by withholding irrigation. Experiments on incorporation with [^{14}C]acetate as the precursor clearly indicate that water deficits provoke a severe inhibition of unsaturated fatty acid biosynthesis. The inhibition of oleate and linoleate desaturation by drought certainly contribute to the decrease in the content of leaf polyunsaturated fatty acids observed in water-stressed cotton leaves (Ouedraogo *et al.*, 1984; Pham-Thi *et al.*, 1985, 1987).

The effect of salt stress such as sodium chloride on lipids is expressed mainly by a decrease of the linolenic acid content (Zarrouk and Cherif, 1984). It seems that a variety of environmental factors can affect polyunsaturated fatty acid synthesis, either directly or indirectly. However, the molecular mechanisms of such changes are obscure, and it is not yet known what role these changes in lipids may play in the adaptation of plants to such environmental stresses.

Conclusion

This review on the current understanding of linolenate production indicates that the process of the biosynthesis of linolenic acid is complex and many fundamental questions remain to be answered. In particular, further studies are needed to establish the substrates for 18:2 desaturation, existence of multiple distinct desaturases, subcellular sites of the desaturation, enzymatic and molecular genetic regulation, and the coordination of different pathways for linolenic acid formation.

Regarding the manipulation of linolenate content in oilseed crops, conventional oilseed breeding has been primarily concerned with the genetic expression of fatty acid composition. But the more that is known of fatty acid and lipid synthesis, the more effectively the breeder can assess the opportunities for oil quality improvement and design the appropriate breeding strategies. Moreover, the rapid development of biotechnology opens additional avenues for the genetic engineering of fatty acid composition of oilseed crops (Knauf, 1987). The scope of possibilities of manipulating storage fatty acids and lipids using genetic engineering is indicated by the diversity of different fatty acid compositions which exist in various types of oilseeds. Plant breeders have already shown that the composition of polyunsaturated fatty acids of two cultivars of an

oilseed crop can differ considerably without obvious effects on agronomic suitability. The modification of seed storage fatty acid composition appears to be feasible, but applied research and product development will depend on gaining a better understanding of the biochemical and genetic processes of lipid biosynthesis. Requisite research for the effective application of biotechnological approaches to the manipulation of lipid composition will be the identification and characterization of the key enzymes controlling lipid composition.

In soybeans, one goal of lipid alteration is to decrease the linolenic acid content in order to increase the stability of soybean oil for cooking purposes. The complexity of linolenic acid biosynthesis within plant tissues and within different parts of a cell present difficult challenges to current biotechniques. In addition, a prerequisite in a genetic engineering project is the ability to monitor the gene of interest and its product. Therefore, by using various approaches, studies in several laboratories are currently endeavoring to identify the gene products involved in the control of 18:3 content (Somerville *et al.*, 1987; Wang *et al.*, 1987 *a* and *b*). Further research will be aimed at isolating those genes. The fact that a number of studies have shown that single gene changes can have a large impact on 18:3 content (Wilcox and Cavins, 1985; Green, 1986; Somerville *et al.*, 1987) is encouraging to the prospects of genetic engineering of plants for altered lipid composition. However, progress along these lines will be complicated unless effective protocols are developed for the purification of the key enzymes (such as linoleate desaturases) controlling linolenate levels in plant tissues.

[34] Stearoyl-Acyl Carrier Protein Desaturase from Safflower Seeds

By TOM MCKEON and PAUL K. STUMPF

Stearoyl-ACP (acyl carrier protein) desaturase is the enzyme responsible for the synthesis of oleic acid in plants. Nagai and Bloch, who first characterized the activity, found that the enzyme requires stearoyl-ACP, reduced ferredoxin, and molecular oxygen.[1,2]

$$\text{Stearoyl-ACP} + \text{ferredoxin(II)} + O_2 + 2H^+ \rightarrow \text{oleoyl-ACP} + \text{ferredoxin(III)} + 2H_2O$$

The stearoyl-ACP desaturase is easily extracted into buffer without the use of detergents, has no requirement for added lipid, and has a lipid-insoluble substrate,[1] all in marked contrast to the stearoyl-CoA desaturase of animal systems.[3] However, because the plant and animal desaturases both require oxygen and an electron transfer system to carry out the same chemical reaction, it is thought that the mechanism of the reaction may be the same for both types of enzyme.

Nagai and Bloch found the stearoyl-ACP desaturase in photosynthetic tissue—*Euglena gracilis* and spinach chloroplasts.[1,2] Subsequently, Jaworski and Stumpf characterized the activity in immature safflower (*Carthamus tinctorius*) seed,[4] a nonphotosynthetic tissue. The activity is also present in avocado mesocarp,[5] immature soybean cotyledons,[6] immature jojoba nuts,[7] and immature coconut.[8] However, this report describes only the stearoyl-ACP desaturase from safflower.

Assay Method

Principle. The assay for stearoyl-ACP desaturase is based on the measurement of ^{14}C-labeled oleic acid produced by desaturation of ^{14}C-labeled stearoyl-ACP. Separation and quantitation of the ^{14}C-labeled fatty acids are carried out by thin-layer chromatography and scintillation counting or by gas–liquid chromatography and radioactive counting in a proportional counter.

Reagents

PIPES, 0.10 *M*, pH 6.0
NADPH, 25 m*M*, freshly prepared in 0.1 *M* Tricine, pH 8.2
Bovine serum albumin (BSA), lipid free, 10 mg/ml in water
Dithiothreitol (DTT), 0.10 *M*, freshly prepared
Ferredoxin, 2 mg/ml (Sigma, spinach, type III)
NADPH: ferredoxin oxidoreductase (Sigma), 2.5 units/ml
Catalase (Sigma, bovine liver, 800,000 units/ml)
[^{14}C]Stearoyl-ACP, 10 μM in 0.1 *M* PIPES, pH 5.8; its synthesis is described after the assay procedure
NaOH, 8 *M*
H_2SO_4, 4 *M*
Stearic acid and oleic acid, 1 mg/ml each in acetone
Petroleum ether
Diazomethane (20 mg/ml in diethyl ether)
$AgNO_3$–silica gel G thin-layer plates, 0.25 mm thick (Redi-Coat AG, Supelco)
2,7-Dichlorofluorescein, 0.1% in methanol

Procedure. The following reagents are added for each assay: water, 150 μl; DTT 5 μl; BSA, 10 μl; NADPH, 15 μl; ferredoxin, 25 μl; NADPH : ferredoxin oxidoreductase, 3 μl; and catalase, 1 μl. This mixture is kept at room temperature for 10 min and is then added to a 13 × 100 mm screw-cap test tube containing 250 μl of PIPES buffer. The stearoyl-ACP desaturase preparation is added in a volume of 10 μl, and the reaction is started by adding 30 μl of stearoyl-ACP and incubating at 23° with shaking for 10 min. The reaction is stopped by adding 125 μl of 8 *M* NaOH and 0.1 ml of the fatty acid solution. The tubes are capped and incubated for 1 hr at 80°. The mixture is acidified with 160 μl of 4 *M* H_2SO_4 and vigorously extracted three times with 2-ml portions of petroleum ether. The extract is evaporated under nitrogen, methylated with 0.5 ml of diazomethane solution for 30 min on ice, and then evaporated to dryness. The methyl esters of stearate and oleate are then separated and quantitated by either of two methods: thin-layer chromatography on $AgNO_3$–silica gel plates as described by Holloway[3] or gas chromatography (10%

DEGS-PS on Supelcoport 80/10; 6 ft. × $\frac{1}{4}$ in. column at 180°) followed by counting of the radioactivity in a gas proportional counter. Radio–gas chromatography avoids the slight complication of correcting for the [^{14}C]palmitate contaminant present in most stearoyl-ACP preparations, but, for accuracy and sensitivity, thin-layer chromatography is the method of choice. One unit of activity is defined as 1 μmol of oleate produced per milligram of protein per minute.

An alternative method for reducing ferredoxin uses a chloroplast grana suspension, ascorbic acid, 2,6-dichlorophenolindophenol, and light. This system has been described in detail by Jaworski and Stumpf.[4]

Stearoyl-ACP Synthesis

Procedure. Stearoyl-ACP is made with a safflower fatty acid synthase system, [^{14}C]malonyl-CoA, and *Escherichia coli* ACP. The method described herein differs only slightly from that described by Jaworski and Stumpf.[9]

Immature safflower seeds are suspended in an equal volume of 0.10 *M* potassium phosphate, 5 m*M* sodium ascorbate, pH 6.8, and are homogenized with a Polytron instrument for three half-minute periods at half speed, centrifuged at 12,000 *g* for 20 min, and filtered through four layers of cheesecloth and one layer of Miracloth. The safflower supernatant is used as a source of fatty acid synthase with no further purification. It is stable when frozen for 6 weeks.[8]

The incubation medium contains the following components in a total volume of 5 ml: water 2.2 ml; 25 m*M* NADH, 100 μl; 25 m*M* NADPH, 100 μl; 1.0 *M* Tricine (K^+), pH 7.9, 250 μl; 0.10 *M* DTT 25 μl; 200 m*M* $MgCl_2$, 25 μl; 1.0 m*M* malonyl-CoA, 1.0 ml; [1,3-^{14}C]malonyl-CoA (50–60 mCi/mmol), 10 μCi in 500 μl; and ACP (4 mg/ml), 175 μl. The ACP used is purified from *E. coli* by the method of Majerus *et al.*[10] to 90% purity, and is reduced with 1 m*M* DTT for 15 min just prior to use. The reaction mixture is carefully bubbled with nitrogen for 5 min; 625 μl of safflower supernatant are added, then the mixture is again bubbled with nitrogen for a minute, stoppered, and placed in a 23° water bath. The reaction is stopped after 45 min by the addition of 0.55 ml of 50% trichloroacetic acid (TCA) in the hood and bubbled with nitrogen to displace $^{14}CO_2$; it is held on ice for 30 min and centrifuged at 5000 *g* for 5 min. The pellet is redissolved in 2.5 ml of 0.10 *M* PIPES, pH 5.8, titrating with 1 *M* KOH if necessary; debris is removed by centrifugation, and solid ammonium sulfate is added

[9] J. G. Jaworski and P. K. Stumpf, *Arch. Biochem. Biophys.* **162**, 166 (1974).
[10] P. W. Majerus, A. W. Alberts, and P. R. Vagelos, this series, Vol. 14 [6].

to 70% saturation (0°). The precipitate is centrifuged at 12,000 g for 10 min, and the supernatant is acidified with 50% TCA to 10%. The TCA precipitate is dissolved in 1 ml of PIPES buffer as before; insoluble material is removed by centrifugation, and the concentration of the stearoyl-ACP is adjusted to 10 μM. This preparation provides 25–40% of the theoretical yield of ^{14}C in acyl-ACP. The product, as analyzed by radio-gas chromatography and $AgNO_3$–silica gel TLC, contains 80–90% stearoyl-ACP, 10–20% palmitoyl-ACP, and less than 0.5% oleoyl-ACP. Frozen solutions of acyl-ACP are stable for over 2 months.

An alternative method for making acyl-ACP of specific chain length is the acyl-ACP synthetase reaction described by Spencer *et al.*[11] Since a specific fatty acid may be ligated to the ACP with this sytem, it has been used to make the substrates employed in specificity studies. However, this system does not efficiently ligate stearic acid to ACP (2–4%) in our hands; therefore, the fatty acid synthase reaction is routinely used to produce substrate for desaturase assays. Another method for making acyl-ACP is described in this volume [21].

Purification

Materials

Immature safflower seed, Gila variety, harvested at approximately 14–18 days after flowering, as indicated by a charcoal gray seed coat

Acetone, reagent grade, −20°

Diethyl ether, anhydrous

DEAE-cellulose, equilibrated with 0.02 M potassium phosphate, pH 6.8

ACP-Sepharose 4B, 2 mg of ACP per milliliter of wet gel; the column material was made with purified *E. coli* ACP, and cyanogen bromide activated Sepharose 4B by the method of March *et al.*[12] The reaction was carried out at pH 6.5 in 0.1 M $NaHCO_3$ for 1 day at 4°, and 70% of the ACP was covalently bound to the Sepharose

Potassium phosphate buffers, 0.02 M, 0.10 M, and 0.30 M, all pH 6.8, sterilized and degassed

Procedure

Acetone Powder. Immature safflower seeds (stored at −20°) are ground with an equal volume of acetone at high speed in a blender. The suspen-

[11] A. K. Spencer, A. D. Greenspan, and J. E. Cronan, Jr., *FEBS Lett.* **101**, 253 (1979).

[12] S. C. March, I. Parikh, and P. Cuatrecasas, *Anal. Biochem.* **60**, 149 (1974).

sion is suction-filtered, and the retained material is repeatedly extracted with acetone as above until the filtrate is clear and colorless. After the third extraction, the acetone suspension is passed through a coarse sieve to remove fragments of seed coat. Generally, five extractions are required to remove the lipids and phenolics. After the final filtration, the retained material is rinsed several times with a small volume of ether at $-20°$ to remove acetone, and then is kept under suction or in a vacuum desiccator to remove the last trace of ether. Stearoyl-ACP desaturase is stable in frozen seeds for at least 2 years and in the acetone powder for at least 3 months.

The following steps are carried out at 0–4°.

Acetone Powder Extract. Acetone powder from a given weight of seed is triturated with twice that weight of 0.02 *M* phosphate buffer and gently agitated for 1 hr. The suspension is then centrifuged at 12,000 *g* for 20 min and filtered through Miracloth, the supernatant, which contains the desaturase, is immediately applied to DEAE-cellulose or frozen. The activity in this preparation is stable for 3–4 weeks at $-20°$ or for 1 week at 4°.

DEAE-Cellulose Pass-through. Acetone powder extract is passed through a column of DEAE-cellulose (1 ml bed volume/3 ml extract), and the column is washed with one bed volume of 0.02 *M* phosphate buffer. The pass-through and effluent from the wash are collected. While this step does afford some purification (see the table), its principal purpose is to eliminate an acyl-ACP thioesterase present in the extract. Approximately 80% of the thioesterase is thus eliminated.[8]

ACP-Sepharose 4B column. The capacity of the ACP-Sepharose is 5 ml of DEAE-cellulose pass-through per milliliter of column material. Decreasing this ratio does not improve the percentage yield, and increasing the ratio decreases the percentage yield.

A column with a 20-ml bed volume is loaded at a flow rate of 0.5 ml per

PURIFICATION OF STEAROYL-ACYL CARRIER PROTEIN (ACP) DESATURASE

Acetone powder extract	380	205	0.55	—	—
DEAE-cellulose pass-through	170	162	0.95	79	1.7
ACP-Sepharose 4-B	0.34	38	110	19	200

[a] Protein was determined by the method of O. H. Lowry, N. J. Rosebrough, A. L. Farr, and R. J. Randall, *J. Biol. Chem.* **193**, 265 (1951), using bovine serum albumin as a standard.

minute, washed with two bed volumes of 0.02 *M* buffer and three bed volumes of 0.10 *M* buffer. The stearoyl-ACP desaturase is eluted with 0.30 *M* buffer and collected in fractions of 1.5 ml. The early fractions contain most of the contaminating acyl-ACP thioesterase; the most purified fractions of desaturase contain acyl-ACP thioesterase as 5–10% of the bulk protein.[8] The desaturase activity from this preparation is stable for 1 week at 4°.

Purity. The most purified preparations of stearoyl-ACP desaturase display one prominent band and several minor bands on SDS–gel electrophoresis. By comparing samples containing various amounts of desaturase and thioesterase, it appears that the prominent band corresponds to the stearoyl-ACP desaturase.

Properties

Specificity. At substrate concentrations of 0.3 μM, the stearoyl-ACP desaturase is 40 times more active on stearoyl-ACP than on stearoyl-CoA and 80 times more active than on palmitoyl-ACP.[8] This high specificity for stearoyl-ACP contrasts with the promiscuous activity of the analogous stearoyl-CoA desaturase from animal systems, which is quite active on acyl-CoA containing 13–19 carbon atoms in the acyl chain.[13]

pH Activity Profile. The desaturase is half-maximally active at pH 5.5 and pH 8.5, with the maximum activity at pH 5.5 in acetate buffer. However, activity at a given pH is dependent on the type of buffer, even at constant ionic strength.[8]

Stability. The stearoyl-ACP desaturase appears to be fairly unstable. It is sensitive to pH, losing 50% or more activity irreversibly when incubated at a pH outside the range pH 6.0 to pH 7.5. It is inactivated on heating at 50° for 1 min. It is unstable to dialysis, irreversibly losing 50% to 100% activity. Finally, further attempts to purify or concentrate the eluent from the ACP-Sepharose column result in nearly total loss of activity.[8]

Miscellaneous Properties. The concentration of oxygen required for maximum activity is 320 μM, which is slightly higher than the oxygen concentration in air-saturated incubation medium, namely 280 μM at 23°; half-maximum activity occurs at a concentration of 60 μM.[8]

Catalase is not required for the desaturase reaction to occur; however, it does stimulate the reaction fivefold. Presumably, catalase protects the desaturase system by scavenging H_2O_2. Both the desaturase and the ferredoxin, NADPH : ferredoxin oxidoreductase system are partially inac-

[13] H. G. Enoch, A. Catala, and P. Strittmatter, *J. Biol. Chem.* **251**, 5095 (1976).

tivated by 0.1 mM H_2O_2, and catalase partially reverses this inactivation.[8] However, two other enzymatic H_2O_2 scavengers do not. Neither horseradish peroxidase nor glutathione peroxidase can replace catalase, and horseradish peroxidase inhibits the desaturation reaction.[8]

[35] Acyl Chain Elongation in Developing Oilseeds

By MICHAEL R. POLLARD

The lipids of most plant tissues contain a narrow spectrum of fatty acids: palmitate, oleate, linoleate, and α-linolenate. The neutral lipids (triacylglycerols)[1] of oilseeds, however, contain a diverse range of fatty acids.[2] One structural variation found is that of acids with chain lengths greater than the usual 16 or 18 carbon atoms. This chapter describes approaches to studying the biosynthesis of acids of chain length C_{20} or greater in developing oilseeds. Some of the considerations noted for the investigation of acyl chain elongation are valid for the investigation of other types of acyl metabolism found in developing oilseeds. Ideally both *in vivo* and *in vitro* experiments are required to demonstrate chain elongation. A radio-gas chromatography machine is useful for detection of ^{14}C-labeled fatty ester.

Supply of Maturing Seed Tissue

The choice of a suitable plant will greatly facilitate the investigation. An ideal plant will exhibit the following features.

1. It should be able to produce a steady supply of developing seeds. That is, a plant is preferred that can be grown and induced to flower all year round, probably in the controlled environment of a growth chamber or greenhouse. A short growth period and early flowering will give maximum experimental flexibility.
2. Larger seeds will help reduce the considerable labor of hand pollination, picking, and removal of the seed coat or pod.
3. For studies on chain elongation, a seed is required that has a high percentage of its fatty acids with a chain length of C_{20} or greater. More than 10% of the dry weight of the mature seed should be lipid

[1] The single exception found in higher plants is the wax esters of jojoba (*Simmondsia chinensis*) seeds [T. W. Miwa, *J. Am. Oil Chem. Soc.* 48, 259 (1971)].

[2] C. Hitchcock and B. W. Nichols, "Plant Lipid Biochemistry," Chapter 1. Academic Press, New York, 1971.

ISBN 0-12-181971-X

in order to measure accurately lipogenic activities *in vivo* and *in vitro*.

Plants that have been used to study the biochemistry of chain elongation in maturing oilseeds are high erucate strains of *Brassica napus* (rape),[3] *Brassica campestris* (turnip rape),[4] and *Brassica juncea* (mustard rape),[5] as well as *Limnanthes alba* (meadowfoam),[6] *Tropaeolum majus* (nasturtium),[7] and *Crambé abyssinica*.[8] They are all annuals. Sometimes, the choice of an oilseed that can be harvested only at a particular time is unavoidable, as in the study of wax ester biosynthesis, which is unique to *Simmondsia chinensis* (jojoba).[9,10] In this case the project becomes distinctly seasonal.

An important preliminary step is to monitor the development of the seeds (Fig. 1). This will ensure that maturing seeds are harvested at the time of maximum lipid biosynthesis. Lipid content (expressed as mass of total or neutral lipid per seed or per gram of fresh or dry seed weight) should be measured as a function of days after flowering (field grown plants) or days after pollination (greenhouse plants). Appelquist has reviewed the topic of lipid accumulation during seed maturation.[11] Several extraction procedures for lipids are suitable. Soxhlet extraction of the dried, ground seeds with petroleum ether will yield neutral lipids.[12] Alternatively, total lipids can be extracted from fresh tissue by homogenizing in petroleum ether–isopropanol, 3 : 2 (v/v)[13] or in chloroform–methanol, 2 : 1 (v/v),[14] followed by the appropriate aqueous salt wash. Extraction of the seed residues should be exhaustive. Developing seeds are ideal for biochemical studies when about 10–50% of the eventual neutral lipid mass has been deposited. Over this period the *in vivo* incorporation of [1-^{14}C]acetate into lipids is generally at a maximum (Fig. 1). Seeds picked later have much endogenous lipid. This can cause severe mass overloading during radio-chromatographic analysis.

ARTICLE

Cloning of Δ12- and Δ6-Desaturases from *Mortierella alpina* and Recombinant Production of γ-Linolenic Acid in *Saccharomyces cerevisiae*

Yung-Sheng Huang[a], Sunita Chaudhary[a], Jennifer M. Thurmond[a], Emil G. Bobik, Jr.[a], Ling Yuan[b,1], George M. Chan[b], Stephen J. Kirchner[a], Pradip Mukerji[a,*], and Deborah S. Knutzon[b]

[a]Ross Products Division, Abbott Laboratories, Columbus, Ohio 43215, and [b]Calgene LLC, Davis, California 95616

ABSTRACT: Two cDNA clones with homology to known desaturase genes were isolated from the fungus *Mortierella alpina*. The open reading frame in one clone encoded 399 amino acids and exhibited Δ12-desaturase activity when expressed in *Saccharomyces cerevisiae* in the presence of endogenous fatty acid substrate oleic acid. The insert in another clone contained an open reading frame encoding 457 amino acids and exhibited Δ6-desaturase activity in *S. cerevisiae* in the presence of exogenous fatty acid substrate linoleic acid. Expression of the Δ12-desaturase gene under appropriate media and temperature conditions led to the production of linoleic acid at levels up to 25% of the total fatty acids in yeast. When linoleic acid was provided as an exogenous substrate to the yeast cultures expressing the Δ6-desaturase activity, the level of γ-linolenic acid reached 10% of the total yeast fatty acids. Co-expression of both the Δ6- and Δ12-desaturase cDNA resulted in the endogenous production of γ-linolenic acid. The yields of γ-linolenic acid reached as high as 8% of total fatty acids in yeast.

Paper no. L8157 in *Lipids 34*, 649–659 (July 1999).

The primary products of fatty acid biosynthesis in most organisms are 16- and 18-carbon compounds. The relative ratio of chain lengths and degree of unsaturation of these fatty acids vary widely among species. Mammals, for example, produce primarily saturated and monounsaturated fatty acids, while most higher plants produce fatty acids with one, two, or three double bonds. Indeed, polyunsaturated fatty acids, such as linoleic acid (Δ9,12-18:2) and α-linolenic acid (Δ9,12,15-18:3), are regarded as essential fatty acids in the diet because mammals lack the ability to synthesize them. However, when ingested, mammals have the ability to metabolize linoleic and α-linolenic acids to form the n-6 and n-3 families of long-chain polyunsaturated fatty acids (LC-PUFA), respectively. These LC-PUFA are important cellular components conferring fluidity to membranes and functioning as precursors of biologically active eicosanoids such as prostaglandins, prostacyclins, and leukotrienes which regulate normal physiological functions (1).

In mammals, the formation of LC-PUFA is rate-limited by the step of Δ6-desaturation, which converts linoleic acid to γ-linolenic acid (GLA, Δ6,9,12-18:3) and α-linolenic acid to stearidonic acid (Δ6,9,12,15-18:4). Many physiological and pathological conditions have been shown to depress this metabolic step, and consequently, the production of LC-PUFA (2). However, bypassing the Δ6-desaturation *via* dietary supplementation with GLA can effectively alleviate many pathological diseases associated with low levels of PUFA (1). This beneficial effect prompted GLA-rich oil to become a much-demanded commodity. GLA is currently used in the treatment of eczema and mastalgia (1). At the present time, the predominant sources of GLA are oils from plants such as borage, evening primrose and black currant, and from microorganisms, such as *Mortierella* spp., *Mucor* spp. and cyanobacteria (3). However, these GLA sources are not ideal for dietary supplementation due to high fluctuations in availability, production/purification costs, unpleasant tastes and odors, and safety concerns. Thus, interest in developing more reliable and economical alternative sources of GLA and other LC-PUFA is growing.

The primary product of fatty acid biosynthesis in most plants and yeast is the monounsaturated, 18-carbon oleic acid. Two desaturation steps, at the Δ12 and Δ6 positions, necessary for the production of GLA from oleic acid, are shown below.

$$\underset{\text{Oleic}}{\Delta 9\text{-}18{:}1} \xrightarrow{\Delta 12\text{-desaturase}} \underset{\text{Linoleic}}{\Delta 9,12\text{-}18{:}2} \xrightarrow{\Delta 6\text{-desaturase}} \underset{\alpha\text{-Linolenic}}{\Delta 6,9,12\text{-}18{:}3}$$

The cDNA clones encoding Δ12-desaturases were isolated from several species of cyanobacteria (4,5) and plants including *Arabidopsis* (6), soybean (7), and parsley (8). Δ6-Desaturase-encoding cDNA were isolated from cyanobacteria (9), borage (10), and nematode (11). These enzymes, as well as numerous examples of Δ15/n-3 desaturases (12,13), are all believed to be integral membrane proteins utilizing an acyl-

Abbreviations: GC, gas chromatography; GLA, γ-linolenic acid; LC-PUFA, long-chain polyunsaturated fatty acid; MS, mass spectrometry; PCR, polymerase chain reaction; TPI, triose phosphate isomerase.

lipid substrate, and with the exception of the cyanobacterial enzymes, requiring cytochrome *b5* for the electron transport. The deduced amino acid sequences of these desaturases show a good deal of similarity, most notably in the region of three histidine-rich motifs that are believed to be involved in iron binding (14).

In this study, we utilized the filamentous fungus, *Mortierella alpina*, as the source for desaturase genes. This approach was based on the fact that this fungus is rich in linoleic acid and its LC-PUFA n-6 metabolites, GLA, and arachidonic acid (Δ5,8,11,14-20:4). Using a strategy based on degenerate oligonucleotide primers designed to amplify sequences present at the second and third His boxes of known acyl lipid desaturases (14), we previously isolated a cDNA clone encoding the *M. alpina* Δ5-desaturase (15). A similar strategy utilizing different degenerate primers was also successful in amplifying the same Δ5-desaturase (16). Such polymerase chain reaction (PCR) approaches are limited, however, by the degree of homology of the target cDNA to the particular primers and conditions utilized. In order to achieve a more thorough examination of the fatty acid desaturases present in the fungus, an alternate approach of sequencing random cDNA clones was also employed. Since it was known that the previously characterized membrane-bound Δ12- and Δ15-desaturases, as well as the available cyanobacterial Δ6-desaturase sequences, showed significant amino acid sequence conservation, particularly in the histidine-rich regions, it was postulated that potential *Mortierella* desaturase cDNA could be recognized based on their deduced amino acid sequences. Indeed, this was the strategy that led to the identification of a borage Δ6-desaturase (11) and a castor oleate 12-hydroxylase (17). Because the first histidine-rich motif (His-box) region can occur from 80 to 160 amino acids (240–480 bp) from the N-terminus, and the third region can be roughly 250–300 amino acids (750–900 bp) into the desaturase sequence (14), 300–400 bp of DNA sequence information obtained from the 5′-end of full-length clones might not contain the regions of highest homology among desaturases. Since at the time this work was initiated, no desaturase sequence was identified from *M. alpina* and it was not known how much homology they might display to known sequences, we chose to obtain information from the internal sequences of cDNA clones instead of the 5′-end of full-length clones.

Expression of the *Mortierella* desaturase candidates was carried out in baker's yeast, *Saccharomyces cerevisiae*. This eukaryotic organism was previously shown to be a suitable host containing the necessary cofactors for functional expression of acyl-lipid desaturases. *Saccharomyces cerevisiae* contains a Δ9-desaturase capable of producing monounsaturated palmitoleic and oleic fatty acids, but does not carry out further desaturations. Expression of an *Arabidopsis FAD2* cDNA in *S. cerevisiae* resulted in the production of linoleic and Δ9,12-hexadecadienoic acids from the endogenous oleic acid and palmitoleic acid substrates, respectively (18,19). By culturing *S. cerevisiae* in the presence of exogenous fatty acid substrates, functional expression of a nematode Δ6-desaturase (11) and a fungal Δ5-desaturase (15,16) were demonstrated. In this study, we report the isolation of Δ12- and Δ6-desaturases from *M. alpina*. Simultaneous expression of these two genes in *S. cerevisiae* drives production of GLA at levels of up to 8% of the total fatty acids without the requirement for exogenous fatty acid substrates.

MATERIALS AND METHODS

cDNA library construction. Synthesis of *M. alpina* cDNA was described previously (15). Briefly, double-stranded cDNA were sized fractionated by column chromatography. The two fractions containing the largest cDNA were pooled and packaged to produce a "full-length" library (M7+8) containing *ca.* 6×10^6 clones with an average insert size of 1.77 kb. An additional library, (M11), to be used for random sequencing was constructed by packaging a fraction containing smaller cDNA, which would most likely contain less than full-length clones as well as full-length copies of shorter messages. The average insert size of this library was 1.1 kb; the titer was 240 pfu/μL. Library screening and plaque purification were carried out with the M7+8 library using standard protocols as described previously (20).

Random DNA sequencing. The cDNA-containing plasmids were excised from the λ-ZipLox clones following manufacturer's recommendations (Life Technologies, Gaithersburg, MD). Bacterial cells were plated on ECLB plates containing 50 μg/mL penicillin. DNA sequence was obtained from the 5′-end of the cDNA insert and compared to the National Center for Biotechnology Information nonredundant database using a BLAST server.

Plasmid construction. For expression in yeast, the *M. alpina* cDNA clones for Δ6- and Δ12-desaturase genes were first modified to create *Eco*RI and *Xho*I restriction sites adjacent to the start and stop codons, respectively. Each gene was amplified from the respective cDNA clone using PCR with a pair of primers which have homology to the 5′-end and 3′-end of the gene (restriction sites underlined):

RO-192 (5′-TAGGCTGAATTC**ATG**GCTGCTGCTCCCAGTGTGAGGACG-3′)

and

RO-193 (5′-AACTGCCTCGAG**TTA**CTGCGCCTTACCCATCTTGGAGGC-3′)

are forward and reverse primers with homology to the sequences around the initiation and termination codons of Δ6-desaturase (Ma524), respectively (shown in bold).

RO-194 (5′-TACCTCGAATTC**ATG**GCACCTCCCAACACTATCGATGCC-3″

and

RO-195 (5′-AACCGTCTCGAG**TTA**CTTCTTGAAAAAGACCACGTCTCC-3′)

are forward and reverse primers homologous to the 5′- and 3′-ends of the Δ12-desaturase (Ma648), respectively.

The *Eco*RI/*Xho*I putative desaturase gene fragments were cloned into the vector pYES2 (Invitrogen, San Diego, CA) for inducible expression under the control of GAL1 promoter

in yeast. This vector contains a selectable marker gene which confers uracil prototrophy in the host. The plasmids containing the putative Δ6-desaturase (Ma524) and Δ12-desaturase (Ma648) genes were designated as pCGR-5 and pCGR-7, respectively. To construct pCGR11 and pCGR12, the Δ6- and Δ12-desaturase coding regions were isolated from pCGR5 and pCGR7, respectively, as *Eco*R1-*Xho*I fragments and cloned into the pYX242 vector (Novagen, Madison, WI) digested with *Eco*R1-*Xho*I. The pYX242 vector contains a marker gene for selection of leucine prototrophy in the host and has the promoter of TPI (yeast triose phosphate isomerase gene), which allows constitutive expression. Co-expression of recombinant Δ6- and Δ12-desaturases can be achieved by simultaneous introduction of pCGR5 with pCGR12 or pCGR7 with pCGR11 in the appropriate host requiring both uracil and leucine for growth.

Yeast transformation and expression. Different combinations of pCGR5, pCGR7, pCGR11, and pCGR12 were introduced into a host strain of *S. cerevisiae*, SC334, which contains a mutation (*regl-501*) that alleviates catabolite repression of GAL1 promoter (21). Transformation was done using the PEG/LiAc protocol as described previously (22). Transformants were selected by plating on synthetic medium plates with appropriate selection (21). Cells containing pCGR5 and pCGR7 were selected on media lacking uracil, whereas the pCGR11 and pCGR 12 constructs were selected on media lacking leucine.

Results from our preliminary studies showed that expression of genes (Δ6- and Δ12-desaturases) was enhanced when cultures were grown in synthetic medium at 15°C. In the present study, colonies of transformants were first grown overnight at 30°C in synthetic media. Overnight cultures (2–4 mL) were then used to inoculate 100 mL of minimal media for studying the activities of recombinant desaturases. Galactose was added at a final concentration of 2% to the medium for induction of GAL1 promoter in the strains containing pCGR5 and pCGR7. When the enzyme substrate was provided as the exogenous fatty acid, the fatty acid was supplemented at a concentration of 25 μM. The culture was grown for 48 h at 15°C, and subsequently harvested by centrifugation. Cell pellets were washed once with sterile *dd* H_2O to remove the media. The host strain transformed with vector alone was used as a negative control in all experiments.

Fatty acid analysis. The extraction of the yeast lipids followed the procedures described previously (15). Briefly, washed yeast pellets were extracted with 15 mL of methanol and 30 mL of chloroform containing 100 μg of tridecanoin. After extraction, the yeast lipids were first saponified, and the liberated fatty acids were methylated. The distribution of fatty acid methyl esters was then analyzed by gas chromatography (GC) using a Hewlett-Packard 5890 II Plus gas chromatograph (Hewlett-Packard, Palo Alto, CA) equipped with a flame-ionization detector and a fused-silica capillary column (Supelcomega; 50 m × 0.25 mm, i.d., Supelco, Bellefonte, PA). In the present study, the quantity of the product formed and the rate of conversion of substrate to product (conversion rate = product/(substrate + product)) were calculated to reflect the expression/activity of a given desaturase in this yeast cell assay system.

The identification of a given novel fatty acid was verified by gas chromatography–mass spectrometry (GC–MS) using a Hewlett-Packard mass selective detector (model 5920) operating at an ionization voltage of 70 eV with a scan range of 20–500 Da. The mass spectra of new peaks were compared with those of authentic standards (Nu-Chek-Prep, Elysian, MN) and those in the database NBS75K.L (National Bureau of Standards).

RESULTS

Isolation of a Δ6-desaturase-like cDNA clone from M. alpina. DNA sequence was obtained from the 5′-end of cDNA in randomly picked clones from the *M. alpina* M11 library. Sequence of one such clone, Ma524, exhibited limited homology to a known *Synechocystis* Δ6-desaturase (9) when compared to the databanks. Overall, the level of homology was low (BLAST score 114; P 4.7×10^{-7}). The partial cDNA was used as a probe to isolate a full-length clone, designated pCGN5532, from the M7+8 library. The cDNA insert in pCGN5532 (GenBank accession AF110510) was 1617 bp and contained an open reading frame encoding 457 amino acids flanked by 70 and 75 bp of 5′- and 3′-untranslated regions, respectively. The deduced amino acid sequence is aligned to that of borage Δ6-desaturase (10) in Figure 1. The three "His-boxes," known to be conserved among membrane-bound desaturases (6,14), were found to be present at amino-acid positions 172–176, 209–213, and 395–399 in this sequence. Similar to other membrane-bound Δ6- and Δ5-desaturases, the final "HXXHH" histidine box motif was found to be QXXHH (11,15,16). The predicted amino-acid sequence from this clone is similar to the Δ6-desaturases from the *Synechocystis* spp. and *Spirulina* spp. (9), the borage Δ6-desaturase (10), the nematode *Caenorhabditis elegans* (11), and a cytochrome *b5*/desaturase fusion protein from sunflower (23). As reported for other Δ5/Δ6 desaturases, the amino terminus of the protein encoded by pCGN5532 was also homologous to cytochrome *b5* proteins.

Isolation of a Δ12-desaturase-like cDNA clone from M. alpina. DNA sequence obtained from the 5′-end of another random clone, Ma648, showed homology to the soybean n-6 desaturase (7). The homology of the partial *M. alpina* sequence was again relatively weak (BLAST score 110, P 2.0×10^{-6}). Analysis of the open reading frames beginning at the 5′-end of Ma648 indicated that the first possible methionine was in frame +1 which was the frame that showed desaturase homology. Alignment of this open reading frame to 5′-sequence of other Δ12-desaturases indicated that the *M. alpina* Ma648 clone was full-length. This cDNA was designated pCGN5533, and no other corresponding clones were obtained by library screening. The 1488 bp cDNA insert in pCGN5533 (GenBank accession AF110509) contains 78 bp of 5′- and 113 bp of 3′-noncoding sequences flanking an open

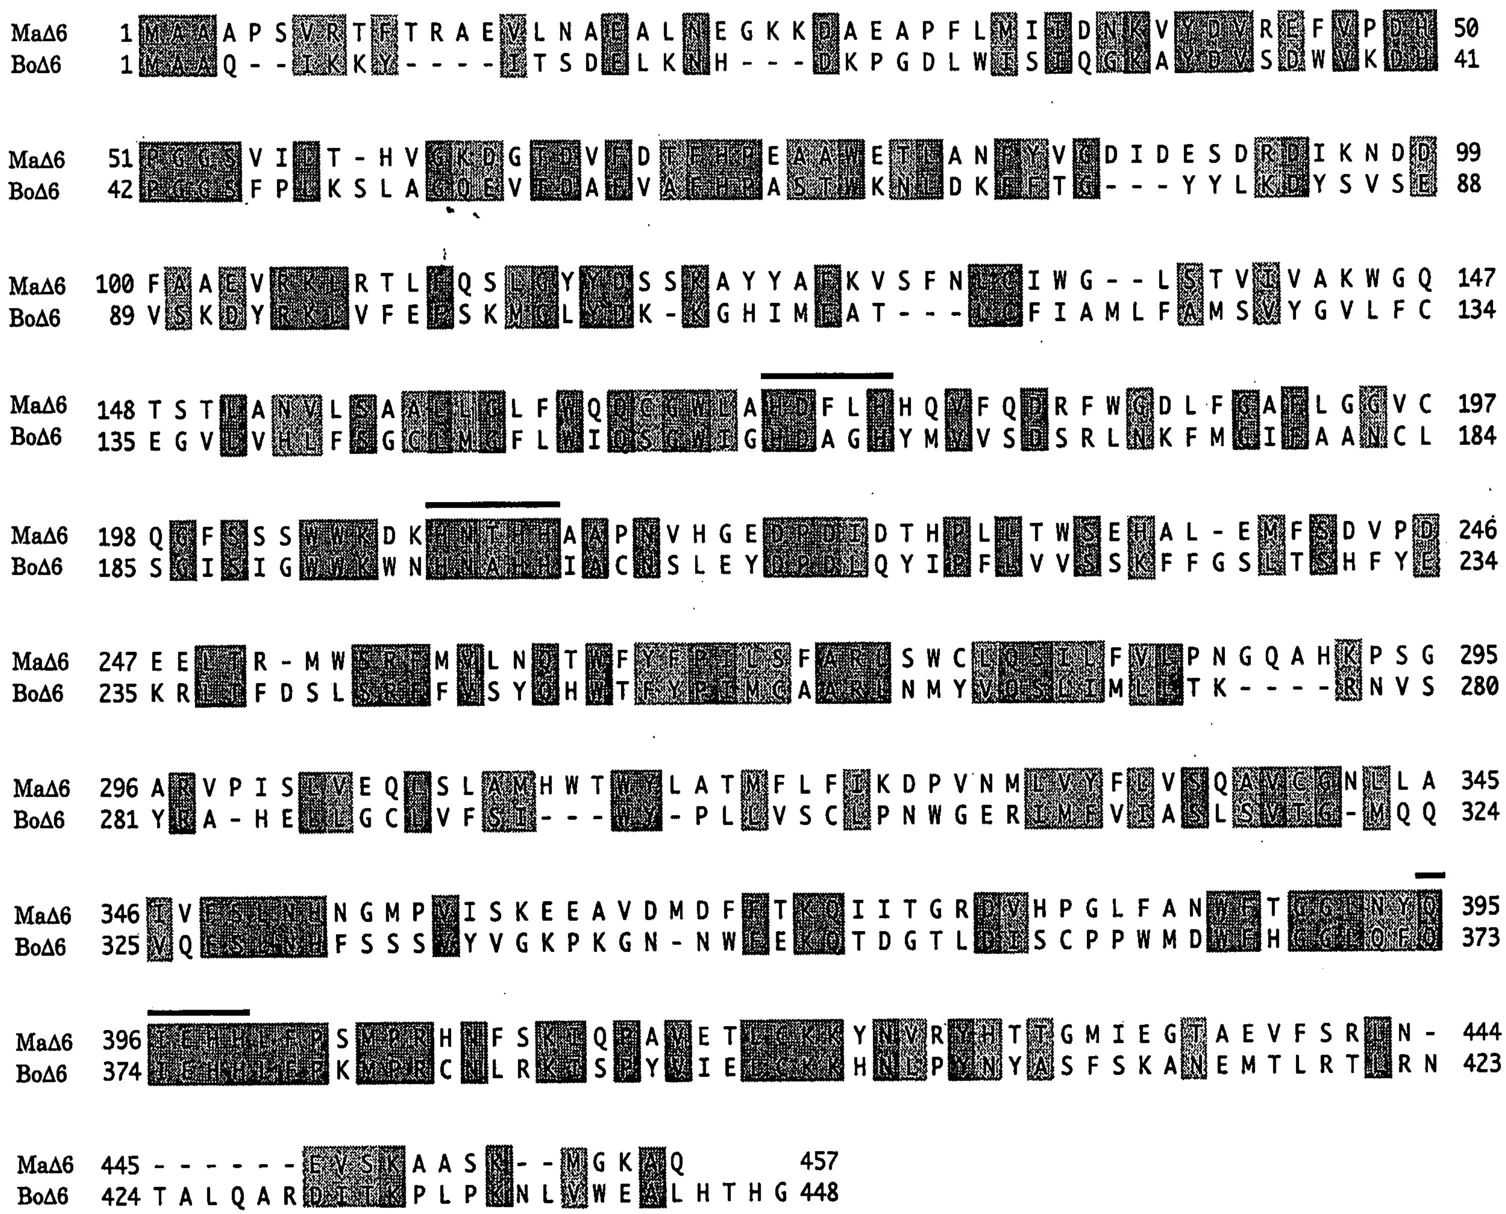

FIG. 1. Comparison of the deduced amino-acid sequences of *Mortierella alpina* and a prototype Δ6-desaturase from borage. Conserved amino acids are shaded light; identical residues are shaded dark. Ma Δ6, *M. alpina* Δ6-desaturase, pCGN5532; Bo 6, Δ6-desaturase from *Borago officinalis* (10). The three regions containing histidine residues (His-boxes) conserved among acyl-lipid desaturases and hydroxylases are overlined.

reading frame encoding 399 amino acids. Figure 2 shows the alignment of the deduced amino acid sequence of pCGN5533 to the *FAD2* (microsomal Δ12 desaturase) from *Arabidopsis* (6). The three His-boxes are again present at positions 111–115, 147–151, and 338–342. Unlike Ma524, no homology to cytochrome *b5* sequence is present on the N-terminus of this clone.

Functional expression of M. alpina *desaturase clone pCGN5533 (Ma648) in yeast.* In order to assess the functional specificity of the various *M. alpina* desaturase clones, the coding regions were expressed in *S. cerevisiae* using the inducible GAL1 promoter found in the commercial vector pYES2. As described previously (15), recombinant yeast cells were grown in the presence of various fatty acids in order to provide substrates for desaturases involved in LC-PUFA production. The deduced coding region of pCGN5533 (Ma648) was inserted into the yeast expression vector pYES2 to create pCGR7. Fatty acid profiles of lipid fractions from yeast grown in the absence of exogenous fatty acid substrate show that two novel fatty acids were produced in SC334(pCGR7) (Fig. 3A). The first fatty acid showed a mass peak $m/z = 266$ (the expected molecular ion of 16:2), a retention time of 13.48 min, and a fragmentation pattern identical to those of Δ9,12-16:2 (Fig. 3B). The second novel fatty acid exhibited a retention time (17.28 min) in GC (Fig. 3A), mass peak (m/z = 294) and fragmentation pattern in GC–MS (data not shown) identical to those of the authentic linoleic acid (Δ9,12-18:2). These findings indicate that the endogenous oleic acid (Δ9-18:1) was converted to linoleic acid (Δ9,12-18:2) by a Δ12-desaturase activity expressed from the plasmid pCGR7. The rate of conversion was found to be 71.4% (Table 1).

Functional expression of M. alpina *desaturase clone pCGN5532 (Ma524) in yeast.* The recombinant yeast SC334(pCGR5), containing the Ma524 cDNA, was grown in the presence of exogenous linoleic acid (Δ9,12-18:2) which is the substrate for Δ6-desaturation. Analyses of the fatty acid profile in the yeast lipid fraction indicate that the exogenous linoleic acid was incorporated into lipids of both nontransformed and transformed yeast (Fig. 4). However, GC analysis revealed the presence of a novel fatty acid in the SC334(pCGR5) yeast that was not present in yeast transformed with vector alone. This novel fatty acid had a retention time of 17.96 min in GC (Fig. 4). Mass peak $m/z = 292$ and fragmentation pattern of this fatty acid in GC–MS were identical to those of the authentic GLA (Δ6,9,12-18:3) standard; however, the fragmentation pattern was different from that of the α-linolenic acid (Δ9,12,15-18:3) standard (data not shown). Thus, the Ma524 cDNA expressed from pCGR5 encodes a Δ6-desaturase. The expressed enzyme converted 29.4% of the incorporated linoleic acid to GLA (Table 1).

Since there were no traces of α-linolenic acid (Δ9,12,15-18:3) produced from the exogenous linoleic acid (Δ9,12-18:2) in the recombinant yeast strains, it is suggested that the enzyme produced by pCGR5 does not possess Δ15-desaturase activity. In addition, when exogenous α-linolenic acid was included in the growth medium, 3.9% of the incorporated α-linolenic acid (Δ9,12,15-18:3) was converted to stearidonic acid (Δ6,9,12,15-18:4). The identity of stearidonic acid was verified by both GC and GC–MS (data not shown). This finding further confirms the enzyme to be a Δ6-desaturase.

TABLE 1
Production of Linoleic Acid and GLA in Yeast Lipid Fraction

SC334 containing	Total fatty acids[a] (μg)	Oleic (wt%)	Linoleic (wt%)	GLA[c] (wt%)
pYES2	440.1	23.2	—	—
pCGR5[b]	497.1	10.2	25.1	10.3
pCGR7	460.9	10.0	24.8	—
pCGR11/pCGR7	340.8	10.2	10.1	7.9
pCGR5/pCGR12	367.9	6.7	7.0	6.6

[a]The volume of culture used for lipid extraction was 100 mL.
[b]Exogenous linoleic acid (25 μM) was added.
[c]No α-linolenic acid was detected. GLA, γ-linolenic acid.

In the absence of exogenous linoleic acid, the lipid fraction of the yeast strain expressing the Δ6-desaturase cDNA produced two novel fatty acids (Fig. 5A). The first novel fatty acid showed a mass peak $m/z = 266$, which is the expected molecular ion of 16:2. Although the GC–MS fragmentation patterns of this novel fatty acid and the authentic Δ9,12-16:2 were similar, they were different in intensity (Figs. 3B and 5B), and retention time (12.89 vs. 13.48 min) in GC (Figs. 3A and 5A). Since this novel fatty acid was produced in the presence of the Δ6-desaturase, it was most probably the Δ6,9-16:2. The second novel fatty acid produced in SC334(pCGR5) had an identical retention time (16.95 min) in GC (Fig. 5A), mass peak $m/z = 294$, and fragmentation pattern in GC–MS to that of the Δ6,9-18:2 standard (data not shown).

Production of GLA. As shown above, the recombinant Δ12- and Δ6-desaturases were effective in converting their substrates (endogenous oleic acid and exogenous linoleic acid) to their respective products, linoleic acid (Fig. 3) in SC334(pCGR7) and GLA (Fig. 4) in SC334(pCGR5). We were interested in determining the feasibility of producing GLA in a recombinant yeast strain in the absence of exogenously added fatty acid substrates. The biosynthesis of GLA from the endogenous oleic acid in *S. cerevisiae* would require the simultaneous expression of Δ12- and Δ6-desaturases. In order to allow co-expression of the Δ6- and Δ12-desaturase cDNA, they were cloned under the control of the constitutive TPI promoter into the leucine-selectable vector pYX242 to create pCGR11 and pCGR12. Both combinations of promoters GAL1 and TPI were assayed for production of GLA. The co-expression of pCGR11 (containing Δ6-desaturase gene under the control of TPI) and pCGR7 (containing Δ12-desaturase gene under the control of GAL1) resulted in *ca.* 7.9% of GLA in total fatty acids of SC334(pCGR7, pCGR11) (Table 1). The rates of conversion from oleic acid to linoleic acid and from linoleic acid to GLA were *ca.* 50 and 44%, respectively. In SC334 (pCGR12, pCGR5) containing the Δ6-desaturase gene behind GAL1 and the Δ12-desaturase gene behind TP1, a level of 6.6% of GLA was found in the total fatty acids (Table 1). In these recombinant yeast strains, the

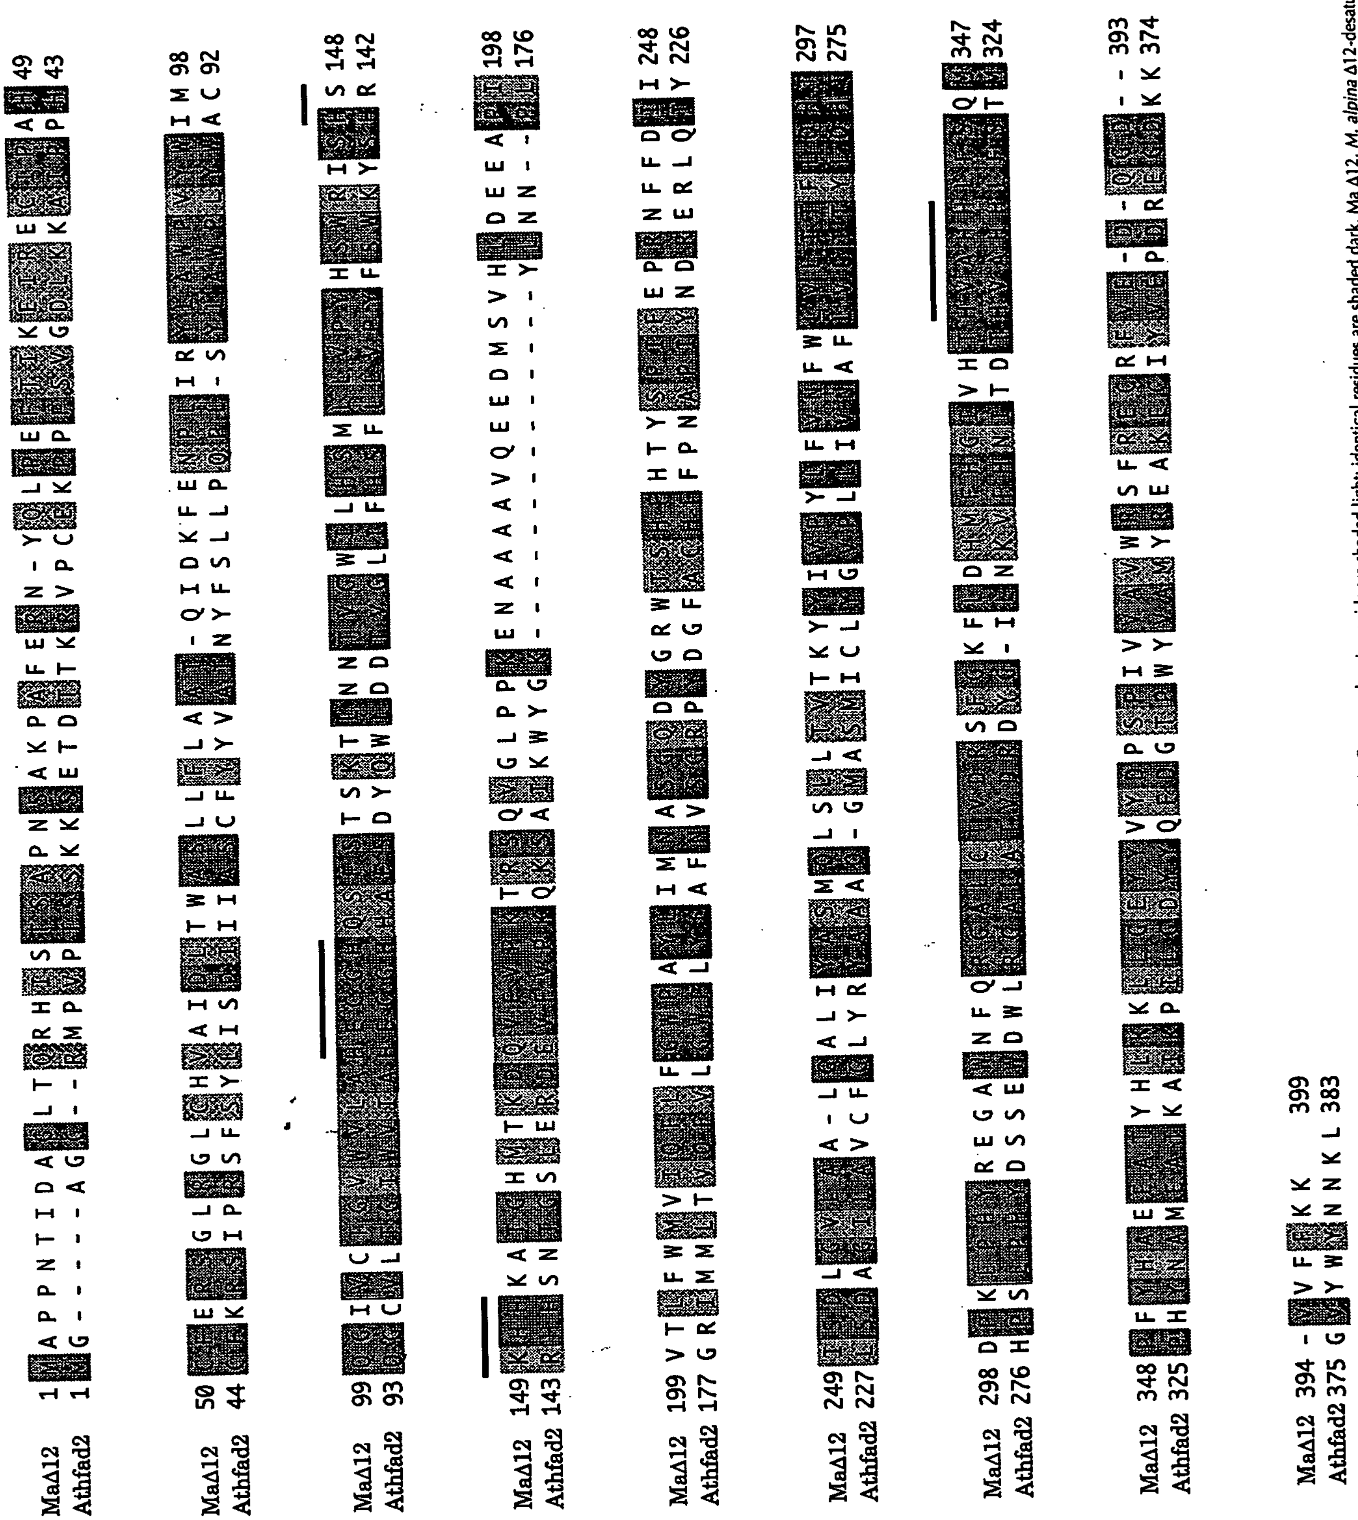

FIG. 2. Comparison of the deduced amino-acid sequences of *M. alpina* and a prototype Δ12-desaturase from *Arabidopsis*. Conserved amino acids are shaded light; identical residues are shaded dark. Ma Δ12, *M. alpina* Δ12-desaturase, pCGN5533; Athfad2, Δ12-desaturase from *A. thaliana* (6). The three regions containing histidine residues (His-boxes) conserved among acyl-lipid desaturases and hydroxylases are overlined. See Figure 1 for abbreviation.

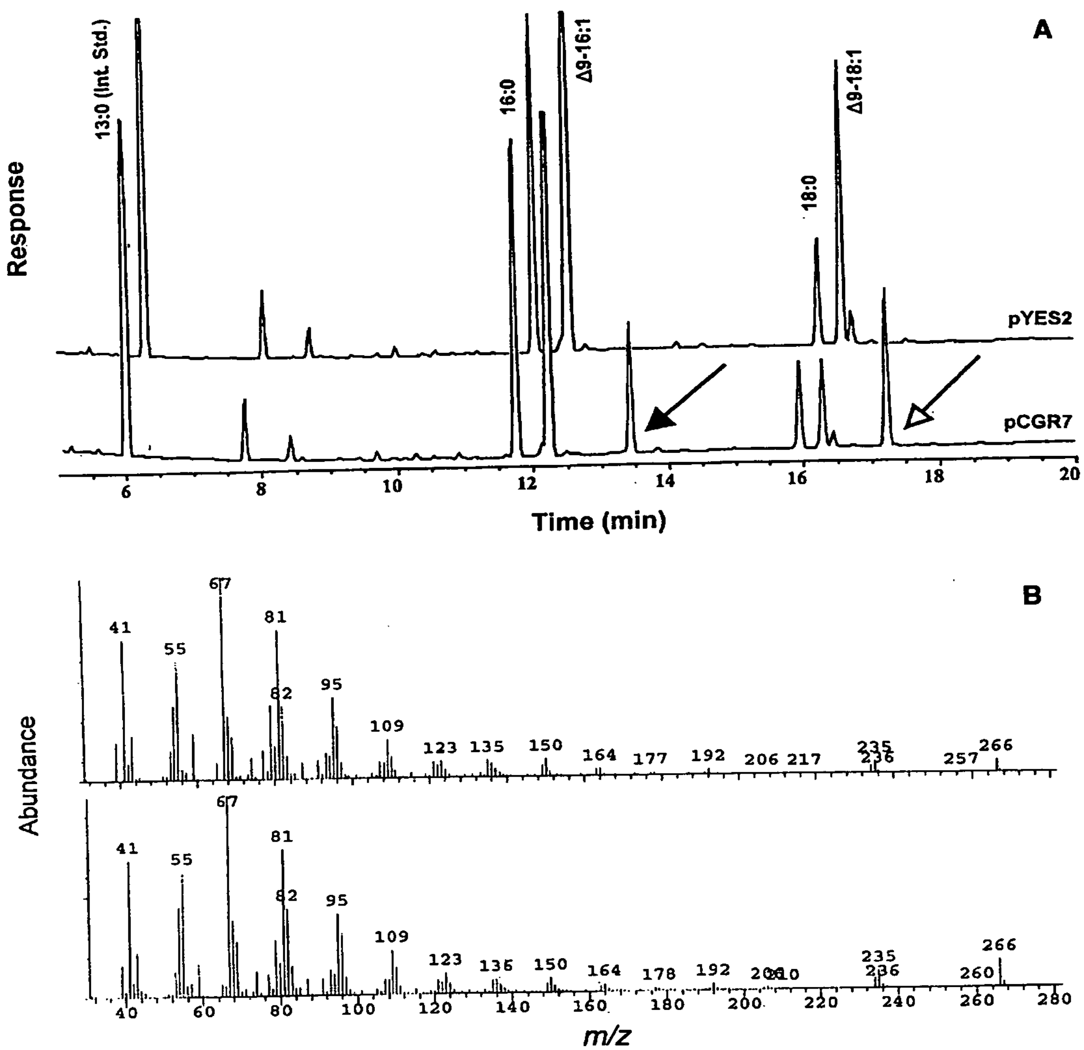

FIG. 3. (A) Gas chromatographic analysis of fatty acid methyl esters (FAME) from the lipid fraction in yeast containing pYES2 or pCGR7. Solid and open arrows indicate the fatty acids Δ9,12-16:2 and Δ9,12-18:2, respectively, present in SC334(pCGR7) cultures. (B) Gas chromatography–mass spectrometry (GC–MS) analysis of the novel peak (identified by the solid arrow in Fig. 3A) in yeast carrying pCGR7. The fragmentation pattern of the first novel peak (top) was compared with that of the authentic Δ9,12-16:2 standard (bottom). pYES2 contained only vector whereas pCGR7 contained the coding region of the *M. alpina* Δ12-desaturase cDNA clone, pCGN5533. All yeast strains were grown in the minimal medium. See Figure 1 for other abbreviations.

conversion rate for both oleic acid to linoleic acid and linoleic acid to GLA was about 50%. Among them, SC334(pCGR11, pCGR7) produced a higher level of GLA, and the GLA accumulated predominantly in the phospholipid fraction (data not shown). Hence, co-expression of *M. alpina* Δ6- and Δ12-desaturase genes under the control of independent promoters in yeast resulted in *de novo* synthesis of GLA.

Comparison of desaturase amino acid sequences. The availability of three desaturase sequences from *M. alpina* was used to examine the interspecies and interclass relationships of these sequences. The amino-acid sequences between the first and third His-boxes of representative desaturases were used to construct a similarity dendrogram (Fig. 6). Two major classes of desaturases can be discerned in this dendrogram. One class contains the Δ12/n-6 and Δ15/n-3 desaturases, while all known examples of Δ5- or Δ6-desaturases fall into a separate class. Although only the central amino-acid core sequence was used in the alignments, all the desaturase sequences with an N-terminal cytochrome *b5*-like sequence cluster into the latter sequence group. The presence of the cytochrome *b5* extension appears to be related to the functionality of the desaturase and not the source of the gene; of the three desaturases from *M. alpina*, only the Δ5- and Δ6-desaturases have the fused cytochrome sequence. In addition, all of the members of this class contain the H-Q substitution in the third His box.

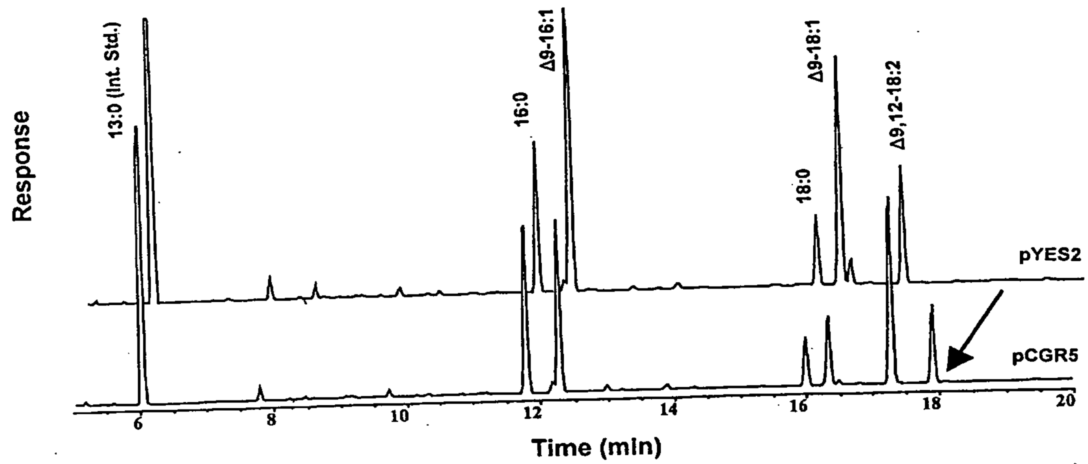

FIG. 4. Gas chromatographic analysis of FAME from the lipid fraction in yeast containing pYES2 or pCGR5. The arrow indicates a novel fatty acid (Δ6,9,12-18:3) present in SC334(pCGR5) cultures. pYES2 contained only vector, whereas pCGR5 contained the coding region of the *M. alpina* Δ6-desaturase cDNA clone, pCGN5532. All yeast strains were grown in minimal medium supplemented with the exogenous linoleic acid (Δ9,12-18:2). See Figures 1 and 3 for abbreviations.

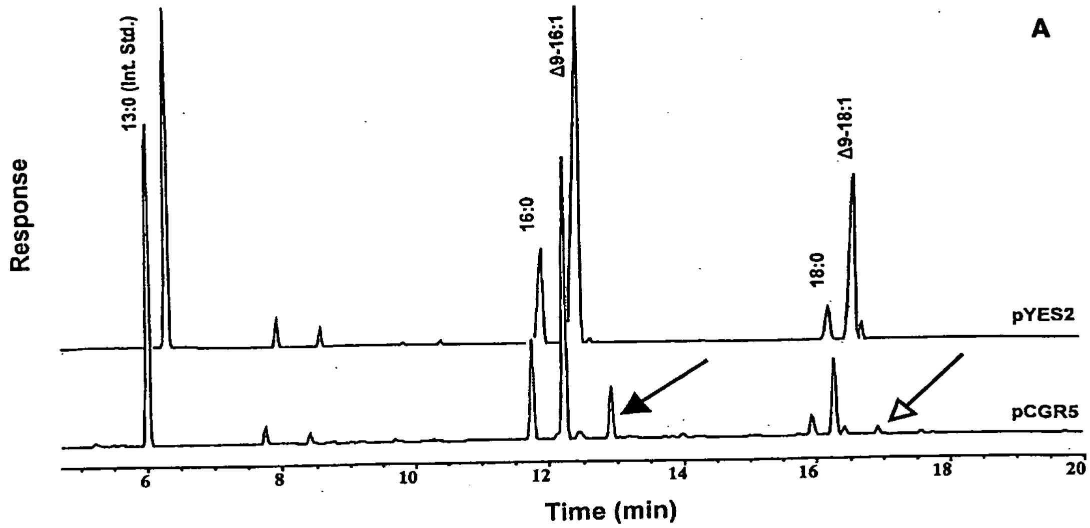
DISCUSSION

We utilized a random sequencing approach to identify cDNA clones encoding fatty acid desaturases from the fungus, *M. alpina*. Partial sequence obtained from the 5′-end of randomly-selected clones was compared to the databanks, and homologies to known acyl-lipid desaturases were noted. This report describes the isolation of two different desaturase-like cDNA clones encoding Δ6- and Δ12-desaturases. These clones were identified in a first-phase sequencing of ~1200 cDNA. In addition to the two clones described in this work, the first phase of sequencing also revealed clones corresponding to the Δ5-desaturase originally obtained by heterologous PCR (15,16) and clones homologous to the yeast stearoyl-CoA desaturase (24) (data not shown). A more thorough sequencing effort of 5400 additional cDNA resulted in the identification of 13 sequences with homology to stearoyl-CoA desaturases, 8 Δ6-desaturases, 9 Δ5-desaturases, and 5 Δ12-desaturases. It should be noted that several of the random clones encoding Δ5- and Δ6-desaturases actually showed cytochrome *b5* matches in the BLAST results, due to the highly homologous cytochrome domain at the N-terminus of these desaturases. Had this domain not been previously identified, several of these cDNA might not have been recognized as desaturases in such a mass sequencing effort. This is an important point to keep in mind when interpreting BLAST results of all sequences; the presence of one highly conserved domain may lead to mis-annotation of the sequence.

The comparison of the desaturase amino-acid sequences shown in Figure 6 indicates that the *M. alpina* Δ5-desaturase is more closely related to the cyanobacterial Δ6-desaturases than to the plant and animal Δ6-desaturase sequences. The ultimate significance of this is hard to evaluate, due to the lack of other Δ5-desaturases for comparison. It should, however, be noted that the *C. elegans* ORF on cosmid T13F2 (GenBank accession number Z81122) that was proposed to be a possible Δ5-desaturase (16) shows more similarity to the *M. alpina* Δ6-desaturase sequence than to the *M. alpina* Δ5-desaturase sequence (data not shown).

In the present study, we showed that the recombinant enzyme expressed by a *M. alpina* desaturase-like gene (Ma648) in pCGR7 converted Δ9-16:1 to Δ9,12-16:2 and oleic acid (Δ9-18:1) to linoleic acid (Δ9,12-18:2) (Fig. 3A). These findings clearly demonstrated that this gene encodes the Δ12-desaturase. We also showed that the recombinant enzyme expressed by another *M. alpina* gene (Ma524) in pCGR5 converted n-6 fatty acid linoleic acid (Δ9,12-18:2) to GLA (Δ6,9,12-18:3) (Fig. 4). When an n-3 fatty acid, α-linolenic acid (Δ9,12,15-18:3), was used as the substrate, the SC334(pCGR5) produced the expected product, stearidonic acid (Δ6,9,12,15-18:4) (data not shown). In the absence of linoleic acid as substrate, this recombinant enzyme could convert the endogenous Δ9-16:1 to Δ6,9-16:2, and oleic acid (Δ9-18:1) to Δ6,9-18:2 (Fig. 5A). These findings demonstrate that this gene encodes the Δ6-desaturase.

In order to evaluate the feasibility of producing GLA—a high-value PUFA in this microorganism, we co-expressed the genes encoding Δ6- and Δ12-desaturases in yeast. When both genes were presented in a single construct in yeast, and expressed from a single promoter, GAL1, none of these transformed yeast strains produced a significant amount of GLA (data not shown). Therefore, it seemed likely that two independent promoters would be needed for the concurrent expression of these two desaturases. Indeed, when these desaturases were co-expressed *in trans* from two independent promoters, GAL1 and TPI, the production of GLA reached as high as 8% of the total lipids in yeast grown without exogenous substrates (Table 1). By the action of two separate pro-



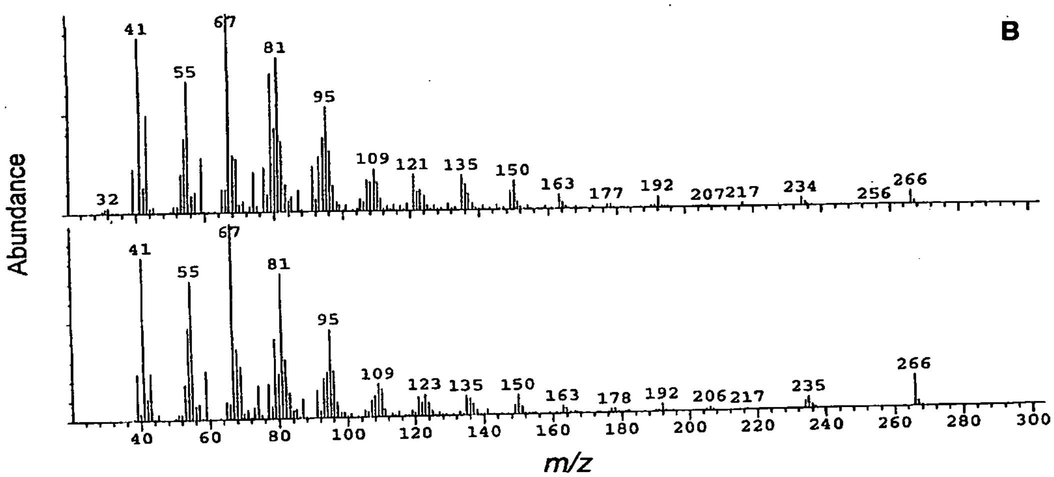


FIG. 5. (A) Gas chromatographic analysis of FAME from the lipid fraction in yeast containing pYES2 or pCGR5 grown without exogenous substrate. Solid and open arrows indicate novel fatty acids Δ6,9-16:2 and Δ6,9-18:2, respectively. (B) GC–MS analysis of the novel peak (identified by the solid arrow in panel A) in yeast carrying pCGR5. The fragmentation pattern of the first novel peak was compared with that of the authentic Δ6,9-16:2 standard pYES2 contained only vector, whereas pCGR5 contained *M. alpina* cDNA clone encoded with Δ6-desaturase. See Figures 1 and 3 for abbreviations.

moters, these enzymes were able to effectively convert (*ca.* 50%) their respective substrates to products.

In summary, we isolated two cDNA from *M. alpina* encoding the Δ6- and Δ12-desaturase genes using a random sequencing-based strategy. The identities of the two cDNA confirmed by functional expression and analysis in a widely used microorganism, baker's yeast. By introducing the two required desaturases (Δ6- and Δ12-) under the control of independent promoters in yeast, we developed a novel approach to synthesize GLA.

cells, although the number of endogenous *XMyoD* transcripts is much less than that normally found in the myotomes (Table 1).

Do animal caps isolated from *XMyoD*-injected embryos show other signs of muscle differentiation? The *XMyoD*-injected animal caps are histologically indistinguishable from uninjected or *XMyoD114P*-injected controls (Fig. 3*a, c, d*). By contrast, uninjected animal caps induced by vegetal tissue elongate and contain large blocks of muscle (Fig. 3*b*). We obtained intense labelling of this muscle tissue using the 12/101 anti-muscle antibody[21], but saw no labelling above background of the *XMyoD*-injected animal cap cells (Fig. 3). We conclude that no differentiated muscle is formed by *XMyoD*-injected animal caps. Thus, animal cap cells that contain as much cardiac actin RNA as normal myotomal cells do not express the full myogenic programme, but continue to differentiate as epidermis. Whole *XMyoD*-injected embryos also develop relatively normally, becoming tadpoles with substantially normal external and internal structures, including a variety of differentiated cell types (data not shown).

We have shown that XMyoD can activate a muscle gene to its normal level in animal cap cells. MyoD can bind to sites in the promoters of muscle genes[2], and we note that, in addition to a CArG sequence that is essential for transcription[22], there are potential XMyoD-binding sites[2] located further upstream in the *Xenopus* cardiac actin promoter (M. V. Taylor, N.D.H. and T. J. Mohun, unpublished data). The lack of muscle differentiation in *XMyoD*-injected animal caps could be caused by a failure to maintain a sufficiently high concentration of XMyoD protein. Alternatively, as enough XMyoD has been supplied to activate the cardiac actin gene to its normal level, it may be that muscle did not differentiate because other myogenic factors, not themselves activated by XMyoD, are required to divert these embryonic cells from their normal pathway of differentiation.

Enhancement of chilling tolerance of a cyanobacterium by genetic manipulation of fatty acid desaturation

Hajime Wada, Zoltan Gombos & Norio Murata*

National Institute for Basic Biology, Myodaiji, Okazaki 444, Japan

THE sensitivity (or tolerance) of plants to chilling determines their choice of natural habitat and also limits the worldwide production of crops. Although the molecular mechanism for chilling sensitivity has long been debated, no definitive conclusion has so far been reached about its nature. A probable hypothesis[1,2], however, is that chilling injury is initiated by phase transition of lipids of cellular membranes, as demonstrated for cyanobacteria, which serve as a model system for the plant cells[3,4]. Because the phase transition temperature depends on the degree of unsaturation of fatty acids of the membrane lipids[5], it is predicted that the chilling tolerance of plants can be altered by genetically manipulating fatty-acid desaturation by introducing double bonds into fatty acids of membrane lipids. Here we report the cloning of a gene for the plant-type desaturation (termed *desA*). The introduction of this gene from a chilling-resistant cyanobacterium, *Synechocystis* PCC6803, into a chilling-sensitive cyanobacterium, *Anacystis nidulans*, increases the tolerance of the recipient to low temperature.

A mutant in fatty-acid desaturation of membrane lipids of the transformable cyanobacterium, *Synechocystis* PCC6803, was isolated as described previously[6]. This mutant, termed Fad12, is defective in the activity of desaturation that introduces a second double bond at the Δ^{12} position of the C_{18} fatty acids of membrane lipids[6]. It grows much slower at low temperatures (such as 22 °C) than the wild type[6].

TABLE 1 Composition of major fatty acids of total membrane lipids in various strains of *Synechocystis* PCC6803

	Fatty acid (mol %)					
Strain	16:0	18:0	18:1 (9)	18:2 (6, 9)	18:2 (9, 12)	18:3 (6, 9, 12)
Wild type	58	1	8	t	12	17
Mutant (Fad12)	59	1	32	5	t	t
Transformant of Fad12 with *desA* (Bluescript/1.5 kbp)	59	2	9	1	12	14
Transformant of Fad12 with *desA* (pTZ19R/8 kbp)	59	1	8	t	12	15
Transformant of wild type with *desA*::Km^r (Bluescript/1.5 kbp::Km^r)	60	1	32	5	t	t

t, trace amount (<0.4%). Wild type, mutant (Fad12), and transformants of Fad12 with *desA* were grown photoautotrophically at 34 °C as described previously[13]. Transformant of wild type with *desA*::Km^r was cultivated in the same way but in the presence of 5 μg ml^{-1} kanamycin in the culture medium. The disrupted gene, *desA*::Km^r, was constructed by interrupting the *desA* in the cloned Bluescript/1.5 kbp at the *Hin*dIII site by the aminoglycoside 3′-phosphotransferase gene (the kanamycin-resistance (Km^r) cartridge) originating from the bacterial transposon Tn5 (ref. 16). Fatty acids of the total membrane lipids were analysed according to Sato and Murata[17]. The values are the means obtained in three independent experiments, and the deviation of values was within ±1.0%.

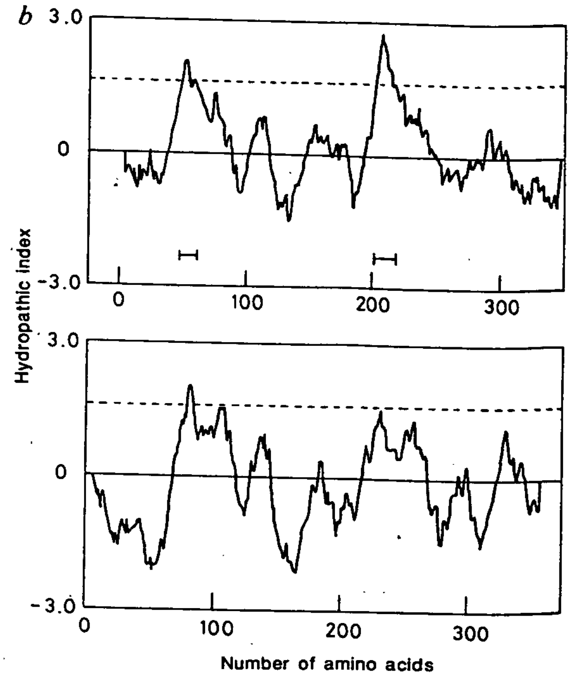

FIG. 1 *a*, Nucleotide sequence and deduced amino-acid sequence of *desA*, a gene for fatty-acid desaturation at the Δ^{12} position of fatty acids in *Synechocystis* PCC6803. The deduced amino-acid sequence is numbered with 1 for the first methionine. *b*, Hydropathy profiles of the deduced amino-acid sequences of the *desA* product and its putative membrane-spanning regions indicated by solid bars (top graph), and the stearoyl-CoA desaturase from rat liver[9] (bottom graph).

METHODS. Nucleotide sequence was determined by the dideoxy chain-termination method using double-stranded DNA templates[18]. The unidirectional deletion of the plasmid was performed according to the instructions of the manufacturer of the Bluescript DNA sequencing system (Stratagene Cloning Systems). Hydropathic index was calculated according to the algorithm of Kyte and Doolittle[19] for a window size of 19 amino-acid residues.

To clone a gene required for the desaturation at the Δ^{12} position, a genomic library of *Synechocystis* PCC6803 was constructed in plasmid pTZ19R. The genomic library was screened for clones capable of complementing Fad12 in the growth at low temperature and the desaturation at Δ^{12} position according to the *in situ* transformation method developed by Dzelzkalns and Bogorad[7]. A plasmid clone with an 8-kilobase pair (kbp) insert, termed pTZ19R/8 kbp, was isolated (Table 1). The homologous recombinations as described by Williams[8] between pTZ19R/8 kbp and the mutated gene of the chromosome of Fad12 may have taken place. The plasmid, pTZ19R/8 kbp, was digested with *Ava*I to obtain a 1.5-kbp fragment, which could also complement Fad12. The 1.5-kbp fragment was subcloned into a Bluescript plasmid (termed Bluescript/1.5 kbp), and its nucleotide sequence was determined. In only one of the six possible reading frames was there an open-reading frame. This was of 1,053 bp and corresponded to 351 amino-acid residues (Fig. 1*a*). The 1.5-kbp fragment also contained a 5′ upstream region of 166 bp and a 3′ downstream region of 270 bp. This gene (termed *desA*) encodes either a plant-type desaturase, which can introduce the second *cis* double bond at the Δ^{12} position of fatty acid bound to membrane glycerolipids, or a cofactor of this desaturase (see below). The hydropathy profile of the deduced amino-acid sequence of the *desA* product (Fig. 1*b*) is similar to that of the stearoyl-CoA desaturase from rat liver[9]. The *desA* gene product has two clusters of hydrophobic regions which are putative membrane-spanning domains (Fig. 1*b*). But, the sequence similarity between the *desA* product and stearoyl-CoA desaturase from rat liver is <30% at the nucleotide level and <10% at the amino-acid level.

We transformed the *Synechocystis* mutant, Fad12, with *desA* included in Bluescript/1.5 kbp and pTZ19R/8 kbp to examine whether the *desA* product is responsible for the fatty-acid desaturation. Table 1 shows that the wild type and the transformants contained high levels of 18:1 (9), 18:2 (9, 12) and 18:3 (6, 9, 12) fatty acids (fatty acids are represented by numbers of carbon atoms and double bonds, before and after a colon, respectively, and the positions of double bonds, counted from the carboxy terminus (Δ), are indicated by numbers in parantheses). In Fad12, 18:1 (9) and 18:2 (6, 9) significantly increased, whereas 18:2 (9, 12) and 18:3 (6, 9, 12) decreased to trace amounts. It is noteworthy that Fad12 lacked the fatty acids having the double bond at the Δ^{12} position, and that this double bond was recovered by transformation with *desA*. Similar changes in the desaturation of fatty acids at the Δ^{12} position were observed in all lipid classes, monogalactosyl diacylglycerol, digalactosyl diacylglycerol, sulphoquinovosyl diacylglycerol and phosphatidylglycerol (data not shown). To examine whether

the *desA* gene product is necessary for fatty-acid desaturation, we transformed the wild-type *Synechocystis* PCC6803 according to Williams[8] with a disrupted *desA*, which was produced by insertion of a kanamycin-resistance cartridge (Km^r). The transformant of wild type with *desA*::Km^r had the same fatty-acid composition as that of Fad12 (Table 1).

Another transformable cyanobacterium, *Anacystis nidulans* R2-SPc, was transformed with *desA* according to Kuhlemeier and van Arkel[10]. It is noteworthy that *A. nidulans* is a member of the group of cyanobacteria, which are completely defective in desaturation at the Δ^{12} position[11,12]. Bluescript/1.5 kbp was digested with *Sac*I to obtain a fragment containing the total sequence of the 1.5-kbp insert. This fragment was subcloned into pUC303 (ref. 10), a shuttle vector between *A. nidulans* and *Escherichia coli*, at the *Sac*I site of the streptomycin-resistance gene but in the opposite direction (termed pUC303/*desA*). The wild-type and the transformant with pUC303 alone (control) contained 16:0, 16:1 (9), 18:0 and 18:1 (9) as the principal fatty acids, indicating that this cyanobacterium can introduce only one double bond into the C_{16} and C_{18} fatty acids (Table 2). In the transformant with pUC303/*desA*, fatty acids having two double bonds, 16:2 (9, 12) and 18:2 (9, 12), emerged to significant levels at the expense of 16:1 (9) and 18:1 (9). The transformation of *A. nidulans* R2-SPc with the disrupted *desA* by the Km^r cartridge was also carried out as above. The transformant with pUC303/*desA*::Km^r had a fatty-acid composition similar to that of the wild type and the transformant with pUC303. The lipid class composition and the lipid-to-protein ratio were not affected by transformation with pUC303 and pUC303/*desA*. These observations demonstrate that the transformant with *desA* has acquired the desaturase activity in introducing the second double bond at the Δ^{12} position of fatty acids, and that the 166-bp upstream sequence contains the promoter region of this gene.

A. nidulans is sensitive to chilling temperature[3,4,13]. At growth temperature, both plasma and thylakoid membranes are in the

TABLE 2 Composition of major fatty acids of total membrane lipids in various strains of *Anacystis nidulans* R2-SPc

	Fatty acid (mol %)					
Strain	16:0	16:1 (9)	16:2 (9, 12)	18:0	18:1 (9)	18:2 (9, 12)
Wild type	51	36	0	3	6	0
Transformant with pUC303	51	37	0	3	5	0
Transformant with pUC303/*desA*	47	29	5	5	2	6
Transformant with pUC303/*desA*::Km^r	50	33	0	5	9	0

Wild type was grown photoautotrophically at 34 °C as described previously[13]. Transformants with pUC303 and pUC303/*desA* were grown in the same way as above but in the presence of 7.5 μg ml^{-1} chloramphenicol. Transformant with pUC303/*desA*::Km^r was grown as wild type but in the presence of 7.5 μg ml^{-1} chloramphenicol and 5 μg ml^{-1} kanamycin. The disrupted gene, pUC303/*desA*::Km^r, was constructed by interrupting *desA* in the cloned pUC303/*desA* at the *Bam*HI site by the Km^r cartridge. Fatty acids were analysed according to Sato and Murata[17]. The values are the means obtained in three independent experiments, and the deviation of values was within ±1.0%. Ten independently obtained transformants with *desA* gave the same result as above.

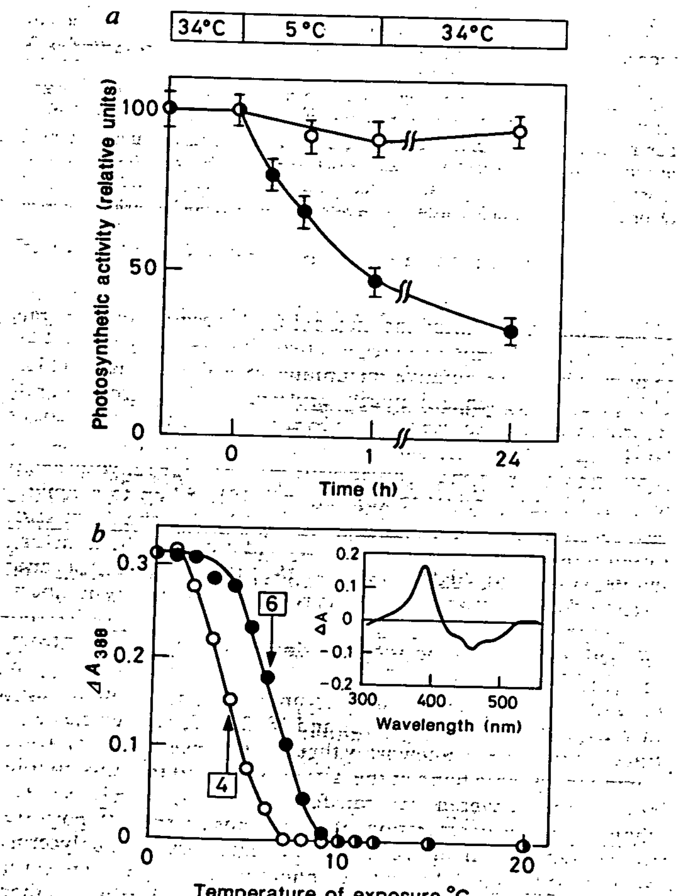

FIG. 2 Effects of low temperature on the photosynthetic activity and phase transition of membrane lipids in the transformants with and without *desA* of *Anacystis nidulans* R2-SPc. ●, Transformant with pUC303; ○, transformant with pUC303/*desA*. *a*, Effect of exposure to 5 °C on the photosynthetic activity. The activity before exposure to 5 °C corresponded to about 190 μmol O_2 per mg chlorophyll per h for both transformants. Each point represents the mean ± s.d. obtained in three independent experiments. *b*, Effect of exposure to low temperature for 20 min on the absorbance change at 388 nm. Inset: changes in absorption spectrum caused by exposure to 6 °C for 20 min in the transformant with pUC303 at a concentration corresponding to 15 μg chlorophyll ml^{-1}. Two independently obtained transformants gave essentially the same result.

METHODS. Cells grown at 34 °C were exposed to low temperature for 20 min in the dark. At an appropriate time the cells were rewarmed to 34 °C, and the photosynthetic activity (light-included oxygen evolution) and the absorption spectrum were measured according to Ono and Murata[13].

liquid-crystalline state. With decrease in growth temperature, the thylakoid membrane first goes into the phase-separated state only with reversible deterioration of photosynthesis. On further decrease in temperature, the plasma membrane enters the phase-separated state, in which leakage of the cytosolic solutes of low relative molecular mass into the medium irreversibly damages physiological activities[3,4].

When the wild type and transformant with pUC303 of *A. nidulans* R2-SPc grown at 34 °C were exposed to 5 °C for 60 min, more than 50% of photosynthetic activity was lost, and further decline of the activity continued after transferring them to 34 °C (Fig. 2*a*). By contrast, the transformant with pUC303/*desA* did not lose photosynthetic activity during the exposure to 5 °C for 60 min (Fig. 2*a*). On exposure to 2 °C for 60 min, the photosynthetic activity was decreased to 40% in the transformant with pUC303 and to 75% in the transformant with pUC303/*desA*. These observations demonstrate that chilling tolerance of *A. nidulans* R2-SPc was enhanced by transformation with *desA*.

The phase transition from the liquid-crystalline to the phase-separated state of the plasma membrane in intact cells of *A. nidulans* can be studied by changes in the absorption spectrum of carotenoids[3,13-15]. The phase transition of the plasma membranes of the transformants containing pUC303 or pUC303/*desA*, both grown at 34 °C, appeared in temperature ranges 8–4 °C with a midpoint at 6 °C, and 6–2 °C with a midpoint at 4 °C, respectively (Fig. 2*b*). The lowering in the phase transition temperature of the plasma membrane by *desA* can be regarded as resulting from the introduced desaturase activity, and this provides a molecular basis for the enhancement of chilling tolerance of this cyanobacterium.

The present study demonstrates that the chilling tolerance of cyanobacteria can be enhanced by genetic manipulation of fatty-acid desaturation. Because a similar mechanism could operate in the chilling injury of higher plants, it might be possible to improve their chilling tolerance by similarly manipulating fatty-acid desaturation. □

Sato of the University of Tokyo for the gift of pUC303 and *A. nidulans* R2-SPc (obtained from Dr W. E. Borrias, University of Utrecht), and Professor T. Slabas (University of Durham) for reading the manuscript.

Partition of tRNA synthetases into two classes based on mutually exclusive sets of sequence motifs

Gilbert Eriani, Marc Delarue*, Olivier Poch, Jean Gangloff & Dino Moras*

Laboratoires de Biochimie et de * Cristallographie Biologique, IBMC du CNRS, 15 rue Rene Descartes, 67084 Strasbourg, France

THE aminoacyl-transfer RNA synthetases (aaRS) catalyse the attachment of an amino acid to its cognate transfer RNA molecule in a highly specific two-step reaction. These proteins differ widely in size and oligomeric state, and have limited sequence homology. Out of the 18 known aaRS, only 9 (ref. 1), referred to as class I synthetases (GlnRS, TyrRS, MetRS, GluRS, ArgRS, ValRS, IleRS, LeuRS, TrpRS), display two short common consensus sequences ('HIGH' and 'KMSKS') which indicate, as observed in three crystal structures[2-4], the presence of a structural domain (the Rossman fold) that binds ATP. We report here the sequence of *Escherichia coli* ProRS, a dimer of relative molecular mass 127,402, which is homologous to both ThrRS and SerRS. These three latter aaRS share three new sequence motifs with AspRS, AsnRS, LysRS, HisRS and the β subunit of PheRS. These three motifs (motifs 1, 2 and 3), in a search through the entire data bank, proved to be specific for this set of aaRS (referred to as class II). Class II may also contain AlaRS and GlyRS, because these sequences have a typical motif 3. Surprisingly, this partition of aaRS in two classes is found to be strongly correlated on the functional level with the acylation occurring either on the 2′ OH (class I) or 3′ OH (class II) of the ribose of the last nucleotide of tRNA.

To clone the ProRS gene, a pool of partially digested *E. coli* DNA fragments was used to transform and complement the strain UQ27 (*proS27, argG, lac, thi*), a temperature-sensitive mutant defective in ProRS activity[5]. From complementing transformants we isolated several types of plasmids, whose insert sizes were reduced by limited *Sau*3A digestion, ligated into plasmid pUC18 vector, and selected in strain UQ27 at 43 °C. The resultant bacterial cells overproduced by 100 times the ProRS activity of wild-type cells. A 2.8-kilobase (kb) DNA fragment was subcloned into M13mp18, partially digested with exonuclease[6] and sequenced using modified T7 DNA polymerase[7]. The 2,795 base pairs (bp) that were sequenced contain an open reading frame encoding a protein of 572 residues whose relative molecular mass (M_r 63,701) is in good agreement with that estimated by SDS-PAGE (data not shown). The N-terminal protein sequence deduced from the primary structure was independently confirmed by sequencing the first 12 N-terminal residues of the purified ProRS. In addition, the *proS* messenger RNA 5′ termini were determined as described in Fig. 1. Analysis of the DNA region downstream of the TGA stop signal revealed a G+C-rich sequence of hyphenated dyad symmetry, centred on position +1,739 and followed by a run of seven T residues. This structural feature corresponds to a rho-independent termination signal, as indicated by the University of Winconsin Genetic Computer Group (UWGCG) TERMINATOR program using the algorithm of Brendel and Trifonov[8], which predicted a stop site for RNA polymerase at position +1,755 shown in Fig. 1.

The comparison of the ProRS sequence with other aaRS sequences showed extensive homologies with ThrRS (19.2% of strict identity and 44.8% of conservative substitutions as defined in the legend of Fig. 2, not considering the 110 amino-acid insert of ProRS) and with SerRS (13.7% of strict identity and 37.2% of conservative substitutions). An alignment of these three proteins is presented in Fig. 2. ProRS and ThrRS have both longer C-terminal domains than SerRS, whereas ThrRS has a long extension at its N terminus, as compared with ProRS and SerRS. Is this extension implicated in the autoregulation of the ThrRS translation, a unique feature of this aaRS? As already shown[9], this mechanism proceeds through an interaction between the ThrRS and a tRNA^{Thr} anticodon-like structure located upstream of the AUG initiation codon of *thrS*. More recently, however, several results[10] pointed to the existence, at the level of *thrS* operon, of a further domain interacting with ThrRS and whose

The *OLE1* Gene of *Saccharomyces cerevisiae* Encodes the Δ9 Fatty Acid Desaturase and Can Be Functionally Replaced by the Rat Stearoyl-CoA Desaturase Gene*

(Received for publication, June 12, 1990)

Joseph E. Stukey‡, Virginia M. McDonough§, and Charles E. Martin¶

From the Nelson Biological Laboratory, Bureau of Biological Research, Rutgers University, Busch Campus, Piscataway, New Jersey 08855-1059

Strains of *Saccharomyces cerevisiae* bearing the *ole1* mutation are defective in unsaturated fatty acid (UFA) synthesis and require UFAs for growth. A previously isolated yeast genomic fragment complementing the *ole1* mutation has been sequenced and determined to encode the Δ9 fatty acid desaturase enzyme by comparison of primary amino acid sequence to the rat liver stearoyl-CoA desaturase. The *OLE1* structural gene encodes a protein of 510 amino acids (251 hydrophobic) having an approximate molecular mass of 57.4 kDa. A 257-amino acid internal region of the yeast open reading frame aligns with and shows 36% identity and 60% similarity to the rat liver stearoyl-CoA desaturase protein. This comparison disclosed three short regions of high consecutive amino acid identity (>70%) including one 11 of 12 perfect residue match. The predicted yeast enzyme contains at least four potential membrane-spanning regions and several shorter hydrophobic regions that align exactly with similar sequences in the rat liver protein. An *ole1* gene-disrupted yeast strain was transformed with a yeast-rat chimeric gene consisting of the promoter region and N-terminal 27 codons of *OLE1* fused to the rat desaturase coding sequence. Fusion gene transformants displayed near equivalent growth rates and modest lipid composition changes relative to wild type yeast control implying a significant conservation of Δ9 desaturase tertiary structure and efficient interaction b tw en the rat desaturase and yeast cytochrome b_5.

In animal and fungal cells, monounsaturated fatty acids are synthesized via an aerobic process from saturated fatty acid precursors by a microsomal membrane-bound three-component enzyme system involving cytochrome b_5, NADH-dependent cytochrome b_5 reductase, and the Δ9 fatty acid desaturase (1–3). This complex catalyzes the insertion of a double bond between carbons 9 and 10 of the saturated fatty acyl substrates, palmitoyl (16:0)- and stearoyl (18:0)-CoA, yielding the monoenoic products palmitoleic (16:1) or oleic (18:1) acids. Although higher eukaryotes contain polyunsaturated fatty acids in their membranes, either synthesized endogenously via Δ12 and Δ15 desaturase reactions or obtained from their diet, the Δ9 reaction accounts for all *de novo* unsaturated fatty acid (UFA)[1] production in *Saccharomyces cerevisiae* (4).

Isolation and characterization of fatty acid desaturase enzymes has proved difficult due to their extraordinary hydrophobic nature and tight association with membranes. Although fatty acid desaturation was first described using the yeast Δ9 desaturase system, only animal Δ9 enzymes have been successfully purified to homogeneity (5, 6). At a genetic level, only the DNA sequence for the rat liver and mouse adipocyte genes have been reported and analyzed (7, 8). Those genes were found to encode proteins with 92% identical amino acid sequences.

The Δ9 desaturase from rat liver has been most extensively characterized. It is a protein consisting of 358 amino acids of which 62% are hydrophobic (7). The functional enzyme has an obligate phospholipid requirement and contains one molecule of non-heme iron (5). Effects of chemical modification on enzyme function has suggested that arginyl and tyrosyl residues are involved in the binding of the negatively charged CoA moiety of the substrate and in the chelation of the iron prosthetic group, respectively (9). A truncated rat liver Δ9 enzyme missing 26 residues from the N terminus is also membrane-bound and functional (10).

Yeast mutants bearing the *ole1* allele require oleic acid for growth and were believed to produce a defective Δ9 desaturase suggesting that *OLE1* was the structural gene encoding the enzyme (11). Recently, we isolated and characterized a yeast genomic fragment containing the *OLE1* gene of *S. cerevisiae* (12). Replacement of the wild type gene in haploid cells with a disrupted form of that fragment resulted in a UFA-requiring, nonreverting phenotype.

In this paper we report the DNA sequence of the *S. cerevisiae OLE1* gene and compare the deduced amino acid sequence of the yeast Δ9 fatty acid desaturase with that of the rat liver stearoyl-CoA desaturase primary sequence. Although the proteins encoded are highly divergent, the rat Δ9 desaturase gene functions efficiently in *S. cerevisiae* in place of the native yeast gene. Furthermore, predicted structural features of the two proteins suggest a model for the topology of the Δ9 fatty acid desaturase in the ER membrane.

[1] The abbreviations used are: UFA, unsaturated fatty acid; ORF, open reading frame; ER, endoplasmic reticulum; kb, kilobase(s).

MATERIALS AND METHODS

DNA Manipulations, Media, and Stain—All recombinant DNA manipulations were according to standard methods (13, 43). Plasmid amplifications and bacterial transformations were performed using either *Escherichia coli* strain HB101 or XL1 Blue (Stratagene). Yeast transformations were by the method of Ito *et al.* (14). Growth analysis was performed in synthetic dextrose medium supplemented with the appropriate amino acids (23). The genotype of yeast strain L8-14C is: α, *ole1*Δ::*LEU2, leu2-3, leu2-d112, ura3-52, his4*).

DNA Sequencing—Overlapping DNA fragments lying within the *OLE1* open reading frame were subcloned into pBluescript vectors (Stratagene) in two orientations for sequencing in either direction. Single-stranded DNA squencing templates were prepared by methods supplied by Stratagene. The M13(−20) primer was hybridized to single-stranded DNA templates and DNA sequencing was performed by the dideoxy chain termination method of Sanger *et al.* (15) using the modified T7 DNA polymerase, Sequenase (U. S. Biochemical Corp.). In two cases, *OLE1* internal oligonucleotides were synthesized to facilitate DNA sequence analysis.

DNA Sequence and Deduced Primary Sequence Analysis—*OLE1* DNA sequence and the deduced primary sequence analysis was performed using the Genetics Computer Group (GCG) sequence analysis software package (16). Amino acid sequence of the rat liver stearoyl-CoA desaturase was obtained from GenBank. Primary sequence comparison of the yeast and rat liver Δ9 desaturases was performed using the BestFit analysis program. Hydropathy analysis was according to Kyte and Doolittle (17).

Construction of Modified ole1 Alleles—Alleles *ole1–33* and *ole1–107*, containing stop codons in the 5′ region of the coding sequence, were constructed similarly. YEp352/OLE4.8 was partially digested with *Sal*I or *Nco*I, the cohesive ends were made blunt, and plasmids were religated. Following amplification in *E. coli*, plasmid samples were subject to restriction enzyme analysis. Candidates lacking the relevant restriction site were subject to DNA sequence analysis for verification.

Construction of Episomal and Centromeric Plasmids Bearing the Rat Liver Stearoyl-CoA Desaturase Gene—A 1.2-kb rat liver Δ9 desaturase cDNA fragment encoding residues 3–358, stop codon, and 136 base pairs of the 3′-untranslated region was removed from plasmid pDs3-358 (10) by digestion with *Bam*HI and *Sac*I and inserted into the multiple cloning site of episomal plasmid YEp352. A 1.0-kb yeast genomic fragment encompassing the promoter region, translation initiation codon, and the first 27 codons of the *OLE1* was isolated via *Hin*dIII/*Sal*I digestion and ligated in-frame with the rat desaturase fragment in YEp352. In this final construct, an eight-codon linker derived from the multiple cloning site regions of pUC8 and YEp352 separates the yeast N-terminal codons from the rat desaturase sequence. The predicted size of the fusion gene product is 391 amino acid residues. The yeast-rat fusion gene was then recovered via *Hin*dIII/*Dra*I digestion and ligated into YCp50 using *Hin*dIII and *Nru*I restriction sites. Plasmids bearing the fusion gene were amplified in *E. coli* strain XL1-Blue and used to transform the yeast *ole1* gene-disrupted strain L8-14C.

Lipid Isolation and Fatty Acid Analysis—Lipids were extracted from whole yeast cells by direct saponification (18). Fatty acid methyl esters were prepared by transmethylation with boron trifluoride (19) and analyzed by gas chromatography using a 30-meter capillary column SP-2330 (Supelco) in a Hewlett-Packard 5710A chromatograph as previously reported (12).

RESULTS AND DISCUSSION

General Features of the OLE1 Structural Gene—In a previous report it was shown that a cloned 4.8-kb *Hin*dIII yeast genomic fragment, but not two subclones of that fragment terminating at a central *Kpn*I region, complemented the *ole1* mutation of *S. cerevisiae* (12). From that *Kpn*I junction, overlapping subclones were used to "walk" through the observed open reading frame (ORF) in both directions yielding the sequence strategy presented in Fig. 1. Both strands were sequenced through the entire ORF without ambiguity.

The DNA and deduced amino acid sequence of *OLE1* and flanking nucleotide sequence is shown in Fig. 2. The ORF is 1530 nucleotides long. Translation of the entire ORF would produce a 510-amino acid polypeptide having an approximately molecular mass of 57.4 kDa containing 49.2% hydrophobic and 25.7% charged (10.0% acidic and 15.7% basic) amino acid residues. No consensus *N*-glycosylation sites are present in the deduced amino acid sequence of *OLE1* and the protein does not appear to contain a cleavable N-terminal signal sequence.

Yeast TATA promoter elements are commonly found 40–120 base pairs upstream from transcription initiation sites (20) with an average mRNA leader sequence of 52 nucleotides (21). The *OLE1* promoter region has two consensus TATA promoter elements (TATAAA and TATATA) located at positions −30 and −156 relative to the ORF. A transcription initiation event, directed from the TATATA element located at −156, could yield a transcript having features consistent with the above observations. However, transcription initiation directed from the TATAAA promoter element located at −30 could result in an atypically short, nontranslated leader sequence relative to the first in-frame ATG. Furthermore, there are three additional in-frame ATG codons within the first 400 base pairs of the *OLE1* ORF at positions 56, 61, and 116 that could also serve as potential translation start sites (see Fig. 1). Due to the close proximity of the first ATG codon to the TATA promoter element at −30 and comparison with the rat desaturase (discussed below) that showed no significant similarities in the first 140 amino acids, we were prompted to test for functional *OLE1* products initiating from these downstream sites. Two modified *ole1* alleles were constructed (see "Materials and Methods") that shifted the ORF and introduced translation stop codons at either position 33 (*ole1–33*) or 107 (*ole1–107*). Both in-frame stop codons were positioned before the next available ATG sequence. The *ole1* gene-disrupted yeast strain L8-14C, bearing the deletion allele *ole1*Δ::*LEU2*, was transformed with either of the above alleles on an episomal plasmid and tested for the ability to grow in the absence of exogenous UFAs. (Strains bearing this *ole1* allele were previously shown (12) to completely lack Δ9 desaturase activity as determined by product formation and have limited and finite growth potential (4–5 generations) in UFA-free medium.) In both cases the transformed strain grew only when UFAs were added to the growth medium, which is consistent with the first in-frame ATG codon functioning as the primary site of translation initiation.

Yeast and Rat Liver Δ9 Enzyme Amino Acid Analysis—A computer search of homologies to all current entries in GenBank/EMBL protein data bases identified a single data

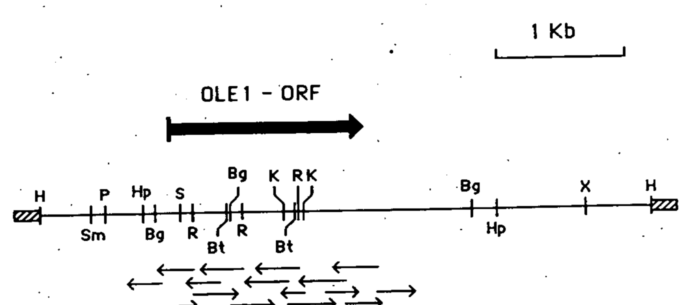

FIG. 1. ***OLE1* restriction map and sequencing strategy.** Primary restriction sites mapping the 4.8-kb yeast DNA fragment containing *OLE1*: *Bg*, *Bgl*II; *Bt*, *Bst*EII; *H*, *Hin*dIII; *Hp*, *Hpa*I; *K*, *Kpn*I; *R*, *Eco*RI; *S*, *Sal*I; *Sm*, *Sma*I; *P*, *Pst*I; and *X*, *Xho*I. FIG. 2. **Nucleotide and encoded amino acid sequence of the Δ9 fatty acid desaturase structural gene, *OLE1*.** Two consensus yeast TATA elements preceding the 1530-base-long ORF and the first four in-frame methionine-specific codons are *underlined*. An *OLE1* internal region of 258 amino acids displaying significant identity to the rat liver Δ9 enzyme is delimited by *asterisks*. Potential membrane-spanning regions are highlighted with *lines* above nucleotide and amino acid sequences.

base entry, the rat liver Δ9 desaturase, with significantly similarity to the *OLE1* gene product (Fig. 3). The aligned sequences show 36% identity and are greater than 60% similar over the region encompassing the C-terminal 260 amino acids of the shorter rat protein. No significant similarities exist over the N-terminal 141 amino acids of the yeast and 99 amino acids of the rat sequences. The yeast open reading frame extends 113 amino acids beyond the C-terminal end of the rat sequence. Within the region of high amino acid similarity there are three segments, having a minimum length of 10 residues, of very high identity (>70%) beginning at *OLE1* amino acid positions 156, 331, and 368. The most highly conserved of these is the first region where 17 of 23 identities are observed including one stretch containing 11 of 12 perfect matches.

The most conserved amino acid type within the compared region of the yeast protein is histidine with 10 of 14 (71.4%) residues in perfect alignment. Two other amino acid residues, proline and arginine, also show greater than 50% total identity. Arginine residues of the rat liver enzyme have been previously identified as being involved in substrate binding

FIG. 3. **Amino acid sequence comparison of the yeast and rat liver Δ9 fatty acid desaturases.** A 257-residue internal region of the yeast Δ9 enzyme is aligned with the rat liver stearoyl-CoA desaturase. Comparison was prepared by the GCG sequence analysis program BestFit. Identical residue matches are indicated by *connecting solid lines*. Two or one point between residues indicate decreasing amino acid similarity. Percent similarity value is based on the number of identical and two-point amino acid comparisons. Segments showing high identity (>70%) are indicated with *lines* above those regions.

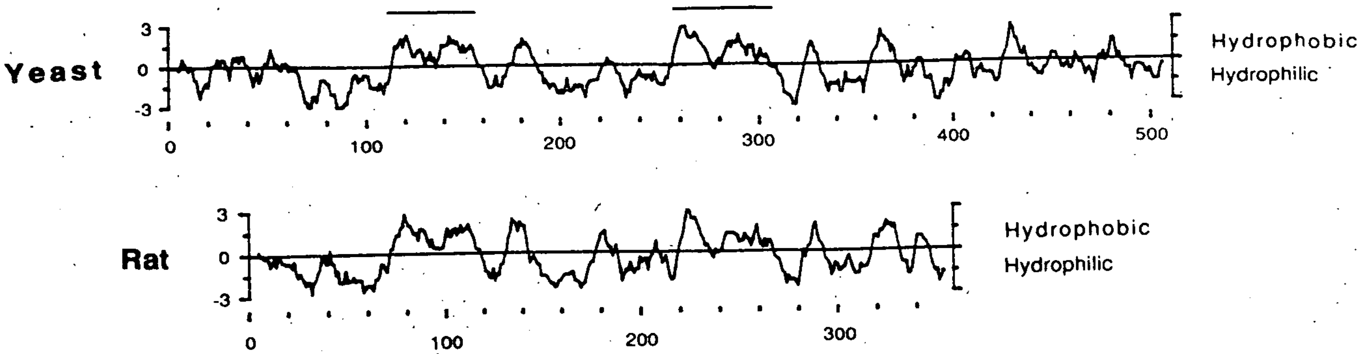

FIG. 4. **Hydropathy analysis of yeast and rat liver Δ9 enzymes.** Aligned Kyte-Doolittle (17) hydropathy profiles of the yeast and rat liver Δ9 desaturase proteins. The presumptive double membrane-spanning sequences are indicated by *bold lines* above those regions.

(9). Its significance as a highly conserved amino acid supports this finding. Although the role of histidyl residues in the fatty acid desaturases has not been examined, their highly conserved appearance also suggests an important contribution to enzyme function.

Structural Analysis and Proposed Topology of the Yeast Δ9 Enzyme—Striking similarities were also observed in the hydropathic characteristics of the two enzymes (Fig. 4). Both proteins contain two long hydrophobic regions (~50 residues) that could potentially form two membrane traversing loops, each consisting of two transmembrane segments. Chou-Fasman algorithms predict β-turn forming potential in the central portions of each loop in both the yeast and rat liver proteins. Inspection of the primary sequences at those sites reveals the presence of multiple helix-breaking amino acids that could serve to disrupt α-helical structure in order to form the looped structures. These hydrophobic regions are at identical positions in the aligned yeast and rat sequences. At least three smaller hydrophobic regions (each <7 amino acids) are also found at identical positions in the two proteins. The regions of high consecutive amino acid identity, however, are not within the hydrophobic sequences. The first region is located between the two "transmembrane loop regions," the second and third identity regions are located at the C-terminal part of the protein past the second "transmembrane loop." Neither extension of the N- and C-terminal domains of the yeast appears significantly hydrophobic and an examination of the amino acid distribution in those regions further suggests that they do not contribute to the integral membrane domains of the protein. A proposed model of the topology of the yeast protein in the ER membrane is given in Fig. 5. Assuming that the membrane-spanning regions are confined to the predicted hydrophobic sequences that are greater than 50 amino acids long, the arrangement places most of the protein on the cytosolic side of the ER membrane. Furthermore, all three regions of high consecutive identity would be located on that side of the membrane which is consistent with its proposed site of action (22).

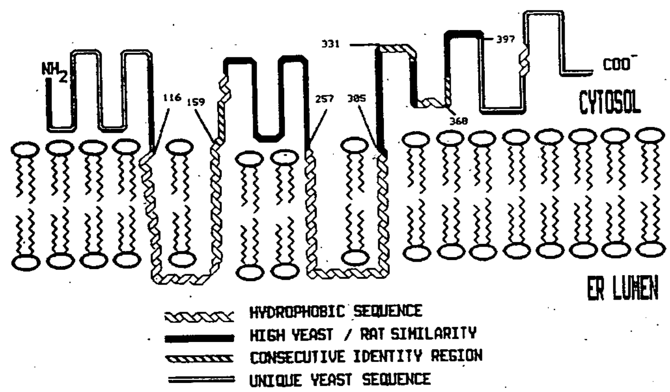

FIG. 5. **Model for the orientation of the yeast desaturase in the ER membrane.** The *numbers* identify amino acid positions in the yeast open reading frame.

Growth and Fatty Acid Content of Gene-disrupted Yeast Transformed with the Rat Liver Δ9 Desaturase—The significant sequence and predicted structural similarities observed between the yeast and rat Δ9 proteins prompted us to test whether the rat enzyme could functionally replace the yeast enzyme in *S. cerevisiae*, although there are additional residues at the N- and C-terminal ends of the yeast peptide sequence that are not found on the rat protein. A yeast-rat fusion gene was constructed (see "Materials and Methods") placing codons 3–358 of the rat gene in-frame with the initial 27 codons of the yeast gene and promoter sequences separated by an 8-codon linker region. This fusion gene was placed on a multicopy episomal and single copy centromere-based (CEN) vectors and introduced into the *ole1* gene-disrupted yeast strain, L8-14C. Fusion gene transformants were analyzed for growth and lipid composition relative to the same gene-disrupted strain transformed with the plasmid bearing native *OLE1* gene.

Yeast transformants bearing either the native *OLE1* or the yeast-rat fusion desaturase gene (two isolates) on an episomal plasmid were found cured of the UFA requirement and, surprisingly, showed identical growth rates (Fig. 6*A*) indicating significant conservation of Δ9 desaturase tertiary structure and an ability of the rat enzyme to interact with the yeast cytochrome b_5. In addition, because the rat protein is 113 residues shorter than the yeast desaturase at the C-terminal end and yet can functionally substitute for the yeast enzyme in *S. cerevisiae*, it appears that this extension of the yeast protein may be nonessential for catalytic functions. We cannot exclude the possibility, however, that the additional residues may be involved in other functions that influence its catalytic efficiency or optimize interactions with other components of the desaturase system.

An analysis of stationary phase cellular lipid compositions revealed, however, significant differences in the percentage of 16-carbon fatty acid species in the yeast-rat fusion gene transformants relative to the wild type control and, as a result, a modest decrease in the percent total UFA (Table I). The lower percentage of 16:1 and increased 16:0 species found in

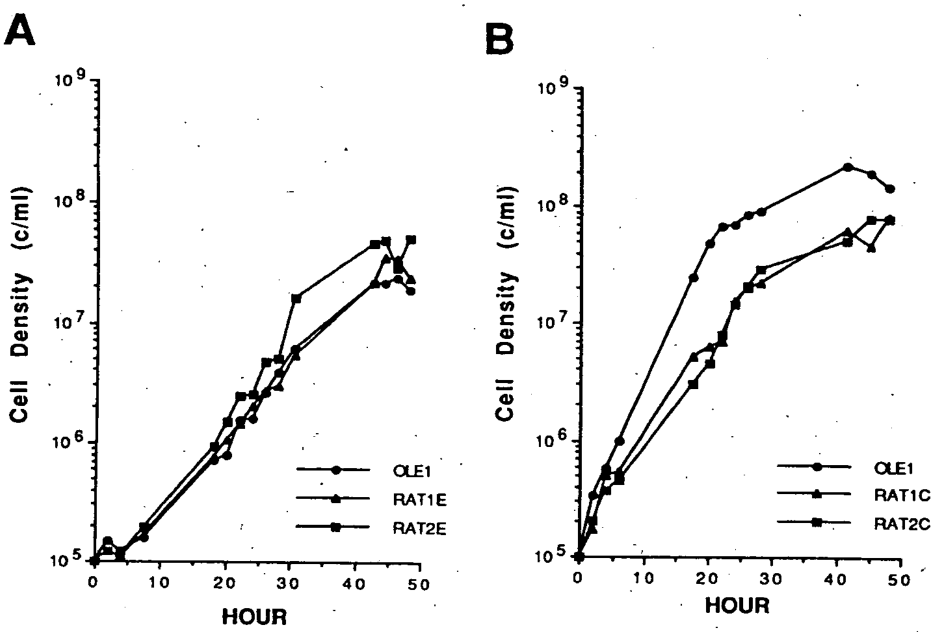

FIG. 6. **Growth characteristics of transformed *S. cerevisiae*.** Growth curves were determined for L8-14C transformants containing either the native *OLE1* gene or the yeast-rat Δ9 fusion gene on the episomal plasmid YEp352 (*A*) or the CEN plasmid YCp50 (*B*).

TABLE I

Fatty acid composition of transformed S. cerevisiae

Stationary phase L8-14C cells transformed with *OLE1* or the yeast-rat Δ9 chimeric gene on multiple (episomal) or single (CEN) copy number plasmids were harvested and cellular lipids analyzed as described under "Materials and Methods."

Plasmid type and transformant	Fatty acids					
	14:0	16:0	16:1	18:0	18:1	UFA
			%			
Episomal						
OLE1	1.95	21.92	41.70	4.65	29.77	71.47
RAT1E	1.40	33.00	28.77	4.61	32.21	60.98
RAT2E	1.41	30.94	27.42	4.73	35.51	62.93
CEN						
OLE1	1.16	18.38	34.05	9.10	37.32	71.36
RAT1C	5.58	40.67	21.22	8.70	23.82	45.04
RAT2C	7.23	39.71	15.83	10.89	26.35	42.18

those strains may reflect a preference of the rat Δ9 enzyme for the 18:0-CoA substrate over 16:0-CoA.

Although a yeast-rat Δ9 desaturase fusion gene is capable of functionally replacing the native *OLE1* of *S. cerevisiae* when present on a high copy number plasmid, a more stringent test of the efficiency of the rat protein in yeast would be to examine cells transformed with a single copy of the fusion gene. Cells containing the chimeric gene on CEN plasmid YCp50 showed growth rates that are reduced approximately 65% relative to wild type (Fig. 6*B*).

Similarly, the lipid composition of CEN plasmid-bearing yeast transformants differed markedly between those containing the chimeric gene and those containing the cloned yeast gene (Table I). The relative UFA levels were reduced approximately 38% in cells containing the rat gene coding sequence and the compensatory relative increase in saturated fatty acids resulted in a doubling of the 16:0 content and increased 14:0 levels, but no significant change in the level of 18:0. Thus, the yeast-rat Δ9 desaturase fusion gene can functionally replace the native *OLE1* of *S. cerevisiae*, although its action results in striking differences in cellular fatty acid compositions.

In previous studies using gene disruption and lipid analytical methods (12) we provided evidence suggesting that the *OLE1* gene encoded the yeast Δ9 fatty acid desaturase. The deduced *OLE1* amino acid sequence and physical comparisons of the yeast and rat liver proteins given here provide further proof that the *OLE1* locus contains the authentic structural gene for the desaturase. The aligned regions of consecutive identity between these two proteins from widely divergent sources suggests that they may represent conserved regions with similar function. The finding that the rat Δ9 fatty acid desaturase gene can complement *OLE1* in *S. cerevisiae* although the two proteins have only 36% identity suggests that there is conserved functional interaction among cytochrome b_5-mediated desaturase systems. Thus, ER-bound Δ9 enzymes from other organisms and possibly other cytochrome b_5-mediated desaturases, such as the Δ12 and Δ15, may also function in yeast.

Acknowledgment—We wish to thank Philipp Strittmatter for plasmids containing the rat stearoyl-CoA desaturase gene.

Received 9 December 1992; accepted in revised form 23 February 1993

Key words: fatty acid desaturation, C_{18} fatty acids, γ-linolenic acid, *Synechococcus* sp. strain PCC 7942

Abstract

The enzyme Δ^6-desaturase is responsible for the conversion of linoleic acid (18:2) to γ-linolenic acid (18:3γ). A cyanobacterial gene encoding Δ^6-desaturase was cloned by expression of a *Synechocystis* genomic cosmid library in *Anabaena*, a cyanobacterium lacking Δ^6-desaturase. Expression of the *Synechocystis* Δ^6-desaturase gene in *Anabaena* resulted in the accumulation of γ-linolenic acid (GLA) and octadecatetraenoic acid (18:4). The predicted 359 amino acid sequence of the *Synechocystis* Δ^6-desaturase shares limited, but significant, sequence similarity with two other reported desaturases. Analysis of three overlapping cosmids revealed a Δ^{12}-desaturase gene linked to the Δ^6-desaturase gene. Expression of *Synechocystis* Δ^6- and Δ^{12}-desaturases in *Synechococcus*, a cyanobacterium deficient in both desaturases, resulted in the production of linoleic acid and γ-linolenic acid.

Introduction

Appropriate control of lipid metabolism is critical to normal cellular and organismal function. In many instances, the number, position, and stereochemical orientation of carbon:carbon double bonds is critical to the biological activity of certain fatty acids. For example, there is considerable interest in the polyunsaturated C_{18} fatty acids: α-linolenic acid ($18{:}3^{\Delta 9,12,15}$) and γ-linolenic acid (GLA; $18{:}3^{\Delta 6,9,12}$). GLA is the result of desaturation of linoleic acid ($18{:}3^{\Delta 9,12}$) catalyzed by the enzyme Δ^6-desaturase. Consumption of vegetable oils rich in GLA may alleviate hypercholesterolemia and other clinical disorders which correlate with susceptibility to coronary heart disease [3]. The therapeutic benefits of dietary GLA may result from its being a precursor to arachidonic acid (20:4) and thus subsequently contributing to prostaglandin synthesis [26].

The nucleotide sequence data reported will appear in the EMBL GenBank and DDBJ Nucleotide Sequence Databases under the accession number L11421.

Most plant seed oils are deficient in GLA; therefore, we investigated the feasibility of obtaining a Δ^6-desaturase gene from a heterologous source which could, in turn, be used to transform plants to obtain seed oils containing GLA. The unicellular cyanobacterium *Synechocystis* PCC 6803 was chosen as a source for the Δ^6 desaturase because *Synechocystis* accumulates GLA to a level greater than 20% of the total fatty acid mass [16] and because the lipid composition of cyanobacteria is similar to that of higher plant chloroplasts [17]. Furthermore, unlike other prokaryotes, cyanobacteria have aerobic desaturases which make them good models for understanding lipid metabolism in higher plants [25].

With the exception of plant Δ^9-stearoyl acyl carrier protein desaturases, cyanobacterial, fungal, plant and animal desaturases are integral membrane proteins, a property that makes them difficult to purify and subsequently clone and characterize [1, 18, 21, 22, 24]. Therefore, we developed a molecular genetic strategy to isolate a Δ^6-desaturase gene from *Synechocystis* PCC 6803. A *Synechocystis* cosmid library was constructed and conjugated into wild-type *Anabaena* PCC 7120, a cyanobacterium deficient in Δ^6-desaturase, to identify gain-of-function *Anabaena* transconjugants that produce GLA and therefore contain a functional *Synechocystis* Δ^6-desaturase gene. With this approach, we cloned a Δ^6-desaturase gene from *Synechocystis* and verified its expression in another cyanobacterium, *Synechococcus* PCC 7942.

Materials and methods

Strains and culture conditions

Synechocystis PCC 6803 was obtained from the American Type Culture Collection. *Anabaena* PCC 7120 and *Synechococcus* PCC 7942 were kindly provided by Dr James Golden and Dr Susan Golden, respectively (Department of Biology, Texas A&M University). These strains were grown photoautotropically at 30 °C in BG-11 medium [19] under illumination of incandescent lamps (60 μE m^{-2} s^{-1}). Cosmids and plasmids were selected and propagated in *Escherichia coli* strain DH5α on LB medium supplemented with antibiotics at standard concentrations [15].

Construction of Synechocystis *cosmid genomic library*

Total genomic DNA from *Synechocystis* PCC 6803 was partially digested with *Sau*3AI and fractionated on a sucrose gradient [2]. Fractions containing 30 to 40 kb DNA fragments were selected and ligated into the dephosphorylated *Bam* HI site of the cosmid vector, pDUCA7 [4]. The ligated DNA was packaged *in vitro* [2], and packaged phage were propagated in *E. coli* DH5αmcr$^-$ containing the helper plasmid, pRL528 encoding *Ava* I and *E. coli* 47II methylases [10]. A total of 1152 colonies were randomly isolated and individually maintained in twelve 96 well microtiter plates.

Conjugation of Synechocystis *cosmid library into* Anabaena

Anabaena cells were grown to mid-log phase in BG-11 liquid medium, washed and resuspended in the same medium to a final concentration of ca. 2×10^8 cells per ml. A mid-log phase culture of *E. coli* containing the RP4 plasmid [5, 10] grown in LB containing 50 μg ampicillin per ml was washed and resuspended in fresh LB medium. *Anabaena* cells were then mixed with *E. coli* containing RP4 and spread evenly on BG-11 plates containing 5% LB. The cosmid genomic library was replica plated onto LB plates containing 50 μg kanamycin and 17.5 μg chloramphenicol per ml and was subsequently patched onto BG-11 plates containing *Anabaena* and *E. coli* carrying the RP4 plasmid. After 24 h of incubation at 30 °C, neomycin was underlaid to a final concentration of 30 μg/ml and incubation at 30 °C was continued until transconjugants appeared [10].

Fatty acid analysis

Wild-type and transgenic cyanobacterial cultures were grown as described [19], harvested by centrifugation, and washed twice with distilled water. Fatty acid methyl esters were prepared from these cultures [8] and were analyzed by gas-liquid chromatography (GLC) using a Tracor-560 equipped with a hydrogen flame ionization detector and capillary column (30 m × 0.25 mm bonded FSOT Superox II; Alltech Associates, IL). Retention times and co-chromatography of standards (obtained from Sigma Chemical Co.) were used for identification of fatty acids. The average fatty acid composition was determined as the ratio of peak area of each C_{18} fatty acid normalized to $C_{17:0}$ internal standard.

DNA sequence analysis

Standard molecular biology techniques were performed as described [2, 15]. Dideoxy sequencing [20] of pBS1.8 was performed with Sequenase (United States Biochemical) on both strands using specific oligonucleotide primers synthesized by the Advanced DNA Technologies Laboratory (Biology Department, Texas A&M University). DNA sequence analysis was done with the GCG (Madison, WI) software [9].

Results

Gain-of-function expression of GLA in Anabaena

Anabaena PCC 7120, a filamentous cyanobacterium, is deficient in GLA but contains significant amounts of linoleic acid, the precursor for GLA (Fig. 2; Table 1). A *Synechocystis* cosmid library was conjugated into *Anabaena* PCC 7120 to identify transconjugants that produce GLA. Individual transconjugants were isolated after conjugation and grown in 2 ml BG11N$^+$ liquid medium with 15 μg neomycin per ml. Fatty acid methyl esters were prepared from cultures containing pools of ten transconjugants and analyzed by GLC; representative GLC profiles are shown in Fig. 2. Two pools (of 25 pools representing 250 transconjugants) were identified that produced GLA. Individual transconjugants of each GLA positive pool were analyzed for GLA production; two independent transconjugants, *AS13* and *AS75*, one from each pool, were identified that expressed significant levels of GLA and which contained cosmids, cSy13 and cSy75, respectively (Fig. 1). These cosmids overlap in a region approximately 7.5 kb in length. A 3.5 kb *Nhe* I fragment of cSy75 was recloned in the vector pDUCA7 to create pSy75-3.5 and transferred to *Anabaena* resulting in gain-of-function expression of GLA (Table 1).

Two *Nhe* I/*Hin*d III subfragments (1.8 and 1.7 kb) of the 3.5 kb *Nhe* I fragment of pSy75-3.5 were subcloned into pBluescript (Fig. 1) for sequencing. Subsequently, both subfragments were transferred into a conjugal expression vector, pAM542 (T.S. Ramasubramanian and J. Golden, personal communication), in both forward and reverse orientations with respect to a cyanobacterial *rbcLS* promoter and were introduced into *Anabaena* by conjugation. Transconjugants containing the 1.8 kb fragment in the forward orientation (pAM542-1.8F) produced significant quantities of GLA and octadecatetraenoic acid (Fig. 2;

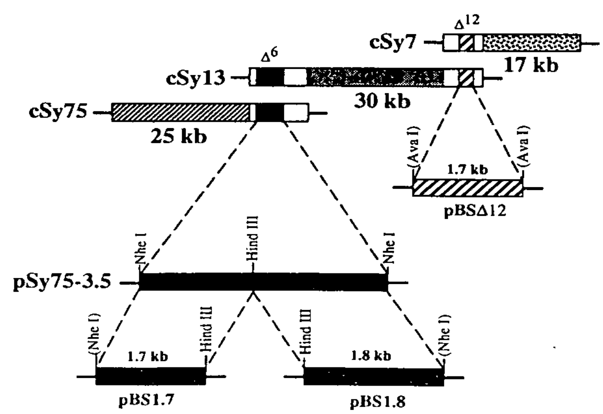

Fig. 1. Maps of cosmid cSy75, cSy13 and cSy7 with overlapping regions and subclones. The origin of subclones of cSy75, pSy75-3.5 and cSy7 are indicated by the dashed diagonal lines. Restriction sites that have been inactivated are in parenthesis.

18:0, stearic acid; 18:1, oleic acid; 18:2, linoleic acid; 18:3(α), α-linolenic acid; 18:3(γ), γ-linolenic acid; 18:4, octadecatetraenoic acid.

Table 1). Transconjugants containing other constructs, either reverse oriented 1.8 kb fragment or forward and reverse oriented 1.7 kb fragment, did not produce detectable levels of GLA (Table 1).

Figure 2 compares the C_{18} fatty acid profile of an extract from wild type *Anabaena* (Fig. 2A) with that of transgenic *Anabaena* containing the 1.8 kb fragment of pSy75-3.5 in the forward orientation (Fig. 2B). GLC analysis of fatty acid methyl esters from pAM542-1.8F revealed a peak with a retention time identical to that of an authentic GLA standard. Analysis of this peak by gas chromatography-mass spectrometry (GC-MS) confirmed that it had the same mass fragmentation pattern as a GLA reference sample (data not shown).

Two genes involved in C_{18} fatty acid biosynthesis are linked

We isolated a third cosmid, cSy7 containing a Δ^{12}-desaturase gene by screening the *Synechocystis* genomic library with an oligonucleotide synthesized from the published *Synechocystis* Δ^{12}-desaturase gene sequence [25]. We identified a 1.7 kb *Ava* I fragment from this cosmid containing the Δ^{12}-desaturase gene and subcloned it into pBluescript to create pBSΔ12 (Fig. 1). We then used this probe to demonstrate that cSy13 not only contains a Δ^{6}-desaturase gene but also a Δ^{12}-desaturase gene (Fig. 1). Genomic filter hybridizations further showed that both the Δ^{6}- and Δ^{12}-desaturase genes are unique in the *Synechocystis* genome indicating that two functional genes involved in C_{18} fatty acid desaturation are linked in the *Synechocystis* genome.

Sequence analysis and comparison with other desaturases

The nucleotide sequence of the 1.8 kb fragment of pSy75-3.5 including the functional Δ^{6}-desaturase gene was determined. An open reading frame encoding a polypeptide of 359 amino acids was

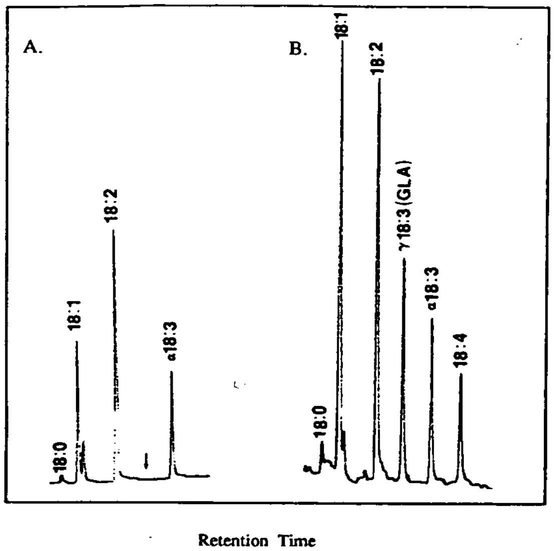

Fig. 2. GLC analysis of fatty acids of wild-type and transgenic *Anabaena*. C_{18} fatty acid methyl esters are shown. A. *Anabaena* wild type (arrow indicates migration time of GLA). B. Transconjugant of *Anabaena* with pAM542-1.8F. GLA, γ-linolenic acid; 18:4, octadecatetraenoic acid. Peaks were identified by comparing the elution times with known standards of fatty acid methyl esters and were confirmed by GC-MS.

identified (Fig. 3). It shares limited, but significant, amino acid sequence similarity with Δ^{15}-desaturase from *Brassica napus* [1] and Δ^{12}-desaturase [25]. A Kyte-Doolittle hydropathy analysis [14] identified two regions of hydrophobic amino acids that could represent transmembrane domains (Fig. 4A); furthermore, the hydropathic profile of the Δ^{6}-desaturase is similar to that of the *Synechocystis* Δ^{12}-desaturase gene (Fig. 4B; [25]), Δ^{9}-desaturase (not shown [23]) and Δ^{15}-desaturase (not shown [1]).

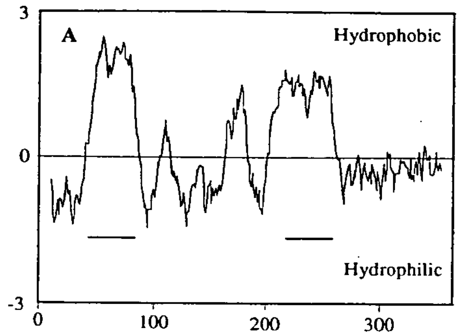
Fig. 3. Nucleotide and predicted amino acid sequences of the *Synechocystis* Δ^{6}-desaturase. Amino acid residues are numbered on the left; nucleotide positions are numbered on the right.

Transformation of Synechococcus *with Δ^{6}- and Δ^{12}-desaturase genes*

The unicellular cyanobacterium *Synechococcus* PCC 7942 is deficient in both linoleic acid and GLA [16]. We cloned Δ^{12} and Δ^{6}-desaturase genes individually and together into pAM854 [6], a shuttle vector that contains sequences necessary for the integration of foreign DNA into the genome of *Synechococcus* [11]. *Synechococcus* was transformed with these gene constructs and colonies were selected [6]. Fatty acid methyl esters were prepared from transgenic *Synechococcus* and analyzed by GLC.

Table 1 shows that the principal C_{18} fatty acids of wild-type *Synechococcus* are stearic acid (18:0)



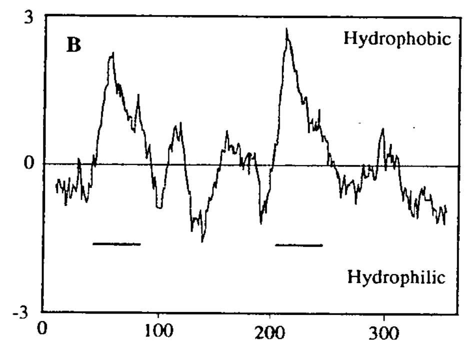


Fig. 4. Hydropathy profiles of (A) Δ^6- and (B) Δ^{12}-desaturase from *Synechocystis*. The Kyte and Doolittle algorithm in the GCG sequence analysis software was used to predict relative hydrophobicity in the predicted polypeptides of Δ^6-desaturase and Δ^{12}-desaturase [9]. Putative membrane-spanning regions are indicated by solid bars.

and oleic acid (18:1). *Synechococcus* transformed with pAM854-Δ12 expressed linoleic acid (18:2) in addition to the principal fatty acids. Transformants with pAM854-Δ6&Δ12 produced both linoleate and GLA (Table 1). These results indicate that *Synechococcus* containing both Δ^{12}- and Δ^6-desaturase genes has gained the capability of introducing a second double bond at the Δ^{12} position and a third double bond at the Δ^6 position of C_{18} fatty acids. However, no changes in fatty acid composition were observed in the transformant containing pAM854-Δ6 indicating that in the absence of substrate synthesized by the Δ^{12}-desaturase, the Δ^6-desaturase is inactive; whether Δ^6-desaturase requires two double bonds or only a double bond at the Δ^{12} position is not clear. This experiment further confirms that the 1.8 kb *Nhe* I/*Hind* III fragment (Fig. 1) contains both coding and promoter regions of the *Synechocystis* Δ^6-desaturase gene.

Discussion

We used a gain-of-function approach to identify a cyanobacterial gene encoding an enzyme involved in fatty acid metabolism. The enzyme Δ^6-desaturase is required for the conversion of linoleic acid ($18{:}2^{\Delta 9,12}$) to γ-linolenic acid ($18{:}3^{\Delta 6,9,12}$) or GLA. Conjugation of a *Synechocystis* PCC 6803 cosmid library into the filamentous cyanobacterium *Anabaena*, which lacks GLA but does contain linoleic acid, the precursor to GLA, resulted in the gain-of-function expression of GLA and octadecatetraenoic acid. The ubiquitous presence of octadecatetraenoic acid ($18{:}4^{\Delta 6,9,12,15}$) in GLA producing transgenic *Anabaena* provides additional insight into the C_{18} desaturation pathway. This unusual fatty acid, which is present normally in fish oils and in some plant species of the Boraginaceae family [12, 13] must result from the further desaturation of α-linolenic acid by a Δ^6-desaturase or desaturation of GLA by a Δ^{15}-desaturase. We further demonstrated that a 1.8 kb region of the *Synechocystis* genome contains both coding and promoter regions of the *Synechocystis* 2Δ^6-desaturase gene and is sufficient to produce GLA in *Anabaena* and *Synechococcus*, although in the latter case only when a second *Synechocystis* gene encoding Δ^{12}-desaturase is also present to generate linoleic acid.

The success of the gain-of-function approach described here, coupled with other molecular genetics tools now available in cyanobacteria, makes possible the identification of other cyanobacterial genes for which there is no selectable phenotype. Certainly, other genes involved in lipid metabolism are prime candidates; the triad of *Synechocystis*, *Anabaena* and *Synechococcus* provide an opportunity to isolate most genes involved in fatty acid metabolism in cyanobacteria. As a consequence, genes encoding desaturases for the

entire C_{18} fatty acid desaturation pathway soon will be available for study. This will facilitate analysis of the factors regulating levels of fatty acid desaturation and the role of these desaturation levels in overall cellular physiology, including chilling tolerance [25]. It is noteworthy that transgenic *Anabaena* and *Synechococcus* with altered levels of polyunsaturated fatty acids were similar to wild type in growth rate and morphology (data not shown) when grown under standard conditions; effects of lower temperatures were not examined. The availability of these genes also will allow detailed structure/function analysis of this class of desaturases and will provide further insight into the evolutionary constraints on protein structure and function.

Recently, transgenic tobacco plants were produced containing a chimeric cyanobacterial desaturase gene, comprised of the *Synechocystis* Δ^6-desaturase gene fused to sequences encoding a carrot extensin signal peptide [7] and an endoplasmic reticulum retention sequence (KDEL); expression of this chimeric gene was driven by a CaMV 35S promoter. These transgenic plants accumulated small but significant amounts of GLA (A.S. Reddy and T.L. Thomas, unpublished results). These results suggest that cyanobacterial genes involved in fatty acid metabolism can be used to generate transgenic plants with altered fatty acid compositions. These modifications could lead to improved nutritional characteristics or increased industrial value of seed oils or improved growth potential of crop plants. In addition, analysis of desaturase expression in a higher plant context may provide insight into the relative role of C_{18} desaturases in the chloroplast, presumably the more natural context of cyanobacterial desaturases, *vis à vis* the endoplasmic reticulum.

Acknowledgements

We are grateful to Dr James Golden and Dr Susan Golden for providing pDUCA7, pAM542 and pAM854 vectors, respectively, and access to their laboratories for the initial part of this work. We thank Dr James Golden and Dr Thomas McKnight for critical review of this manuscript. The work was supported by grants from Rhône-Poulenc Agrochimie, Lyon, France.

TECHNICAL ADVANCE

Stringent repression and homogeneous de-repression by tetracycline of a modified CaMV 35S promoter in intact transgenic tobacco plants

Christiane Gatz*, Claus Frohberg and Regina Wendenburg
Institut für Genbiologische Forschung Berlin GmbH, Ihnestr. 63, 1 Berlin 33, Germany

Summary

A cauliflower mosaic virus (CaMV) 35S promoter derivative, which is tightly repressed by the Tn*10* encoded Tet repressor in a transient expression system as well as in transgenic plants has been constructed. After treatment of transgenic plants with tetracycline (Tc) the activity of the reporter enzyme β-glucuronidase (GUS) increased up to 500-fold in tissue culture as well as under greenhouse conditions. Efficient de-repression was achieved by Tc uptake through the roots as well as by Tc treatment of leaves of intact plants. As Tc is not very stable in the plants, this system can also be used for a transient expression of a transgene. This system provides a unique tool for regenerating transgenic plants carrying a repressed transgene and for efficiently de-repressing its activity by a specific inducer at any time point of further development.

Introduction

The ability to introduce foreign genes into the plant genome has provided the methodology to analyse the molecular mechanisms leading to co-ordinated expression of genes in transgenic plants (Schell, 1987). It also serves to express alien gene products or to modulate the expression of endogenous proteins (Sonnewald *et al.*, 1991). Especially the last option opens new avenues for analysing and understanding the contribution of a defined gene to the organism's phenotype (Berg, 1991). When using this approach, a regulated promoter is often desirable in order to induce expression at defined time points during development, or only in certain parts of a transgenic plant. In addition, a tightly repressed promoter is absolutely required if the expression of a certain gene product of interest interferes with the regeneration process.

A number of plant promoters regulated by light (Kuhlemeier *et al.*, 1987), heat (Ainley and Key, 1990), stress (Freeling and Bennett, 1985), or wounding (Keil *et al.*, 1989) are available for the controlled expression of a transgene. However, they suffer from the disadvantage that the inducing conditions influence a variety of responses in the plants. Therefore we have developed a tightly repressed, specifically de-repressible promoter by a suitable combination of bacterial control elements with a strong, normally constitutive plant promoter.

We have reported previously that the Tn*10* encoded Tet repressor can regulate the expression of a modified CaMV 35S promoter in transgenic tobacco plants (Gatz *et al.*, 1991). In principle, we generated a transgenic plant which constitutively synthesizes the bacterial repressor protein (tetR$^+$). Two binding sites for the Tet repressor, the 19 bp palindromic *tet* operators, were introduced downstream of the TATA-box of the normally constitutive CaMV 35S promoter. When stably integrated into the genome of the *tetR*$^+$ plant, only low levels of activity from this modified promoter were detected. An 80-fold increase in RNA levels was achieved after 0.5 h upon vacuum infiltration of single leaves with a buffer containing the inducer tetracyline (Tc, 0.1 mg l^{-1}), which prevents the repressor from binding to its operator sequences. Since then we have significantly improved the system by a further reduction of the expression in the uninduced stage using a different arrangement of the *tet* operators within the promoter. Moreover, we describe the effect of a variety of Tc application procedures, as well as the kinetics of induction in whole plants and the time course of the decline of the amount of GUS mRNA after omission of the Tc treatment.

Results and discussion

Combination of three tet *operators with the CaMV 35S promoter ('Triple-Op'-promoter)*

It has been proposed by Lin and Riggs that repression efficiencies increase with the number of operators within a promoter, if each copy by itself contributes to repression (Lin and Riggs, 1975). In two previous studies we have investigated the influence of single Tet repressor–operator

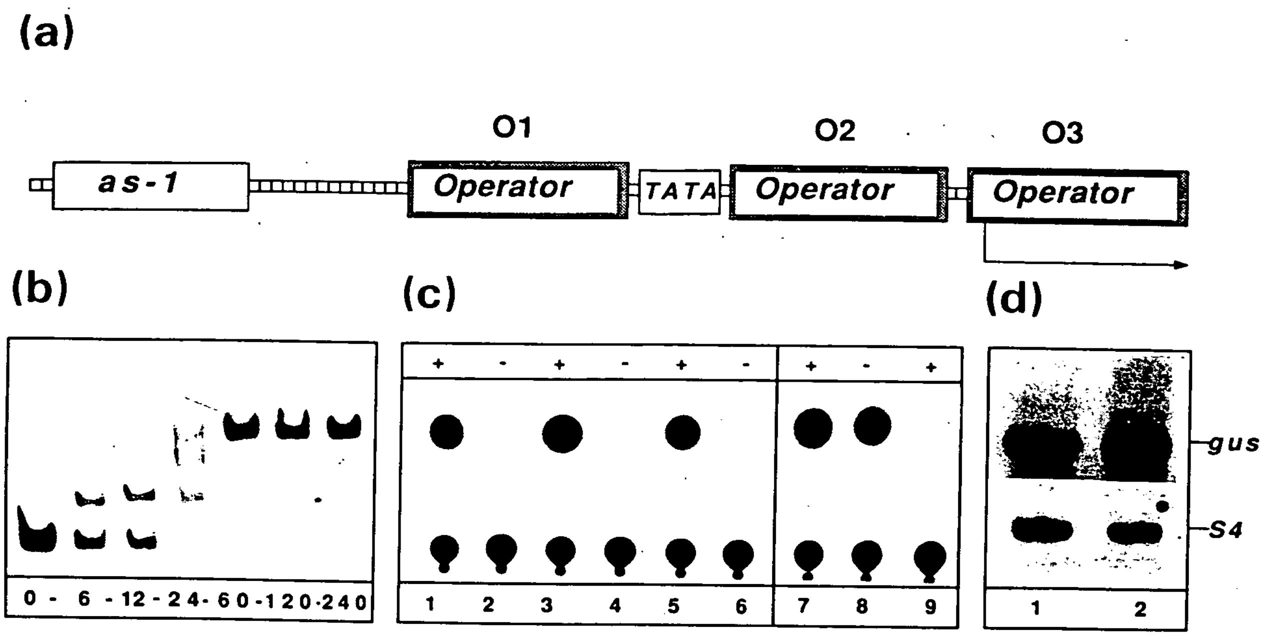

Figure 1. Schematic overview of gel shift analysis, transient expression analysis and Northern blot analysis of the 'Triple-Op' promoter.
(a) Region −90 to +17 of the 'Triple-Op'-promoter. Each square represents 1 bp. The sequence of activating sequence 1 (*as-1*, Lam *et al.*, 1989) is boxed, as well as the three operators (ACTCTATCACTGATAGAGT) and the TATA-box (TATATAA). The arrow marks the start site of transcription (Odell *et al.*, 1985).
(b) Mobility shift experiment demonstrating simultaneous occupation of the three operator sites within the 'Triple-Op'-promoter. One femtomole of a 350 bp fragment containing the complete 'Triple-Op'-promoter was incubated with increasing amounts of Tet repressor purified to homogeneity from *E. coli* (gift of Drs Altschmied and Hillen). Numbers below the lanes indicate the amount (fmol) of Tet repressor added.
(c) Cat activity in transiently transformed tobacco protoplasts which constitutively express the repressor gene (Gatz *et al.*, 1991). Ten micrograms of pTriple-Op-Cat (lanes 1–6) or pTET7 (lanes 7 and 9; Gatz and Quail, 1988) were introduced into tobacco protoplasts using polyethylene glycol mediated gene transfer and incubated with (+) or without (−) Tc. Cat activity shown in lane 9 represents background levels when protoplasts were transformed with herring sperm DNA.
(d) Northern blot analysis of Tc treated transgenic plants containing the chimeric 'Triple-Op'-promoter-GUS-gene (lane 1) or the wild-type CaMV 35S promoter-GUS-gene (lane 2). Rehybridization of the blot with the probe for the ribosomal gene *S4* was done to show that equal amounts of RNA were loaded. RNA from the three highest expressing plants of each transformation was combined for this analysis.

complexes in different positions on the expression of the CaMV 35S promoter (Frohberg *et al.*, 1991; Heins *et al.*, 1992). If located upstream of the TATA-box, efficient repression was only observed when the operator was located less than 3 bp away from the TATA-box. Downstream of the TATA-box the promoter was stringently repressed when the distance between the operator and the TATA-box was not more than 31 bp. In consideration of these data we constructed the so called 'Triple Op' promoter, which contained one operator (O1) 1 bp upstream of the TATA-box, a second operator (O2) 1 bp downstream of the TATA-box and a third operator (O3) 23 bp downstream of the TATA-box (Figure 1a). In Figure 1b we demonstrate that all three operators within this promoter fragment can simultaneously be occupied by the Tet repressor protein, though the spacing of 9 bp between O1 and O2 and the spacing of 2 bp between O2 and O3 is less than in the wild-type arrangement of 11 bp found between the two operator sites in the Tn*10* encoded regulatory region (Hillen *et al.*, 1984). With limiting amounts of Tet repressor four different bands can be observed in a mobility shift assay: free DNA, DNA bound to one repressor dimer, DNA bound to two repressor dimers and a fourth complex representing a fully saturated operator fragment. Next we analysed, in a transient expression system using chloramphenicol acetyl transferase (Cat) as a reporter enzyme (An, 1987), if the combination of the CaMV 35S promoter with three perfectly palindromic operator sequences affected promoter strength. As shown in Figure 1c no significant difference in gene expression was observed when comparing the 'Triple-Op'-promoter in the de-repressed stage with the wild-type CaMV 35S promoter. In the absence of the inducer, no detectable promoter activity was observed in *tetR*$^+$ protoplasts synthesizing the Tet repressor, indicating stringent repression. For the analysis of the promoter in transgenic plants, it was fused to the β-glucuronidase (GUS) gene (Jefferson *et al.*, 1987) and transferred to the genome of a *tetR*$^+$ plant using *Agrobacterium tumefaciens* mediated gene transfer. Leaves from 20 hygromycine resistant regenerated shoots were treated with Tc by vacuum infiltration (Gatz *et al.*, 1991) and GUS activity

was determined. All 20 plants showed no GUS activity before treatment with Tc and in every case a strong increase in GUS activity after Tc treatment. For control purposes a chimeric gene consisting of the wild-type CaMV 35S promoter (Covey and Hull, 1985) and the GUS gene was transferred to tobacco plants. Due to the variation of the expression levels of transgenes (Sanders *et al.*, 1987) we combined RNA from the three highest expressing plants from each transformation and subjected them to Northern blot analysis. As shown in Figure 1d, no difference in gene expression was observed, indicating that maximal wild-type promoter activities can be reached with the 'Triple Op'-promoter in the de-repressed stage.

Quantitation of the repression efficiency of the 'Triple-Op'-promoter in transgenic tobacco plants

At the level of GUS enzyme activity we consistently observed a 50-fold increase of expression after infiltration of single leaves with Tc, which is 10-fold more than we observed with one of our previous constructs which contains only two operators downstream of the TATA-box (Gatz *et al.*, 1991). Because all plants showed the same pattern of Tc dependent gene expression, we kept 10 of the highest expressing plants and randomly picked one of those for the various forms of analysis shown below. When analysing 30 μg total RNA on a Northern blot, we could not detect any GUS RNA in the repressed stage, with longer exposures yielding only background signals from cross-hybridizing ribosomal RNAs (data not shown). In order to quantitate the repression efficiency at the RNA level, we analysed poly(A)$^+$ RNA from repressed and de-repressed leaves of one of the 10 highest expressing transgenic plants. The amount of GUS mRNA in untreated and Tc-treated leaves was compared by using a dilution series of the signal obtained from Tc-treated leaves with mRNA from untransformed plants as a concentration standard. mRNA (800 ng) obtained from untreated and Tc treated leaves was loaded on a gel as well as a mixture (total amount: 800 ng) of poly(A)$^+$ RNA prepared from untransformed tobacco plants with 40, 26, 8, and 4 ng of the mRNA from Tc-treated plants. The signal obtained after rehybridization of the blot with a probe from the ribosomal gene *S4* (Devi *et al.*, 1989) was used to standardize the amount of mRNA loaded. Taking into account that about twofold more poly(A)$^+$ RNA was present in the lane containing mRNA from untreated leaves, we judged from the dilution series shown in Figure 2, that the activity of the 'Triple-Op'-promoter is repressed at least 100-fold at the RNA level.

De-repression of the 'Triple-Op' promoter in whole plants

With the repression efficiency being tight enough to observe significantly different levels of GUS activity in the repressed versus the de-repressed stage we started characterizing different modes of Tc application by doing *in-situ* stainings of whole plants with X-Gluc (Jefferson, 1987). First, we cultivated shoots of one transgenic plant on 2MS-medium supplemented with 1 mg l^{-1} Tc. Tobacco W38 forms roots without delay when grown in the presence of this amount of Tc. As shown in Figure 3a, no GUS activity was observed in the cutting that was grown without Tc even after an overnight incubation in X-Gluc. When grown on Tc-containing medium, however, dark blue staining representing high GUS activity was observed in the roots, the two lower leaves which had been in contact with the medium, and around the vascular tissue in some of the upper leaves. A leaf from a different cutting, which had only partly touched the medium showed staining in this region, and again around the vascular tissue. This result indicates that Tc is taken up through the roots and transported throughout the plant, and that it can also be taken up directly through the leaf. If we let a plant grow on 2MS medium without Tc and place one of the leaves between two separate blocks of agar containing Tc we observe after 6 h a local induction within this leaf. If we extend this treatment for 3 days we observe GUS activity in the lower and upper leaves as well as in the roots, which might indicate that Tc is transported through the phloem.

In order to achieve homogeneous distribution of the antibiotic throughout the plant we removed the lids of our tissue culture containers once a day for 15 min under sterile conditions thus enhancing transpiration. In addition we placed a piece of sterile cheesecloth between the lid and the container which also served to increase transpira-

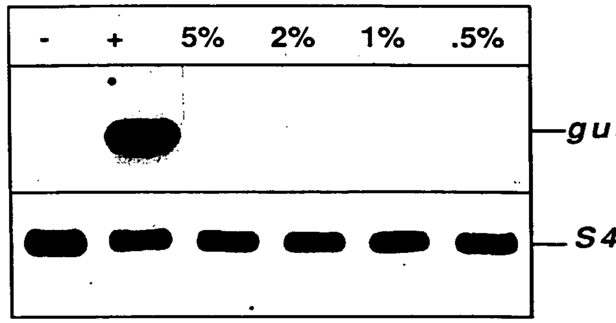

Figure 2. Northern blot analysis of poly(A)$^+$ RNA from a transgenic plant containing a chimeric repressor gene and a 'Triple-Op'-GUS-gene.
Poly(A)$^+$ RNA from an untreated and a Tc treated tobacco plant was analysed, as well as different amounts of poly(A)$^+$ RNA from the Tc treated plant mixed with mRNA from untransformed tobacco W38. Tc treatment was performed by vacuum infiltration of single leaves with 1 mg l^{-1} Tc and RNA was extracted after 2 days. Lane (−): 800 ng RNA from an untreated plant; lane (+): 800 ng RNA from a Tc-treated plant (TcRNA); lane (5%): 760 ng W38 RNA +40 ng TcRNA; lane (2%): 784 ng W38 RNA + 16 ng TcRNA; lane (1%): 792 ng W38 RNA + 8 ng TcRNA; lane (0.5%): 796 ng W38 RNA + 4 ng TcRNA. The blot was hybridized first with a GUS probe and afterwards with a *S4* probe.

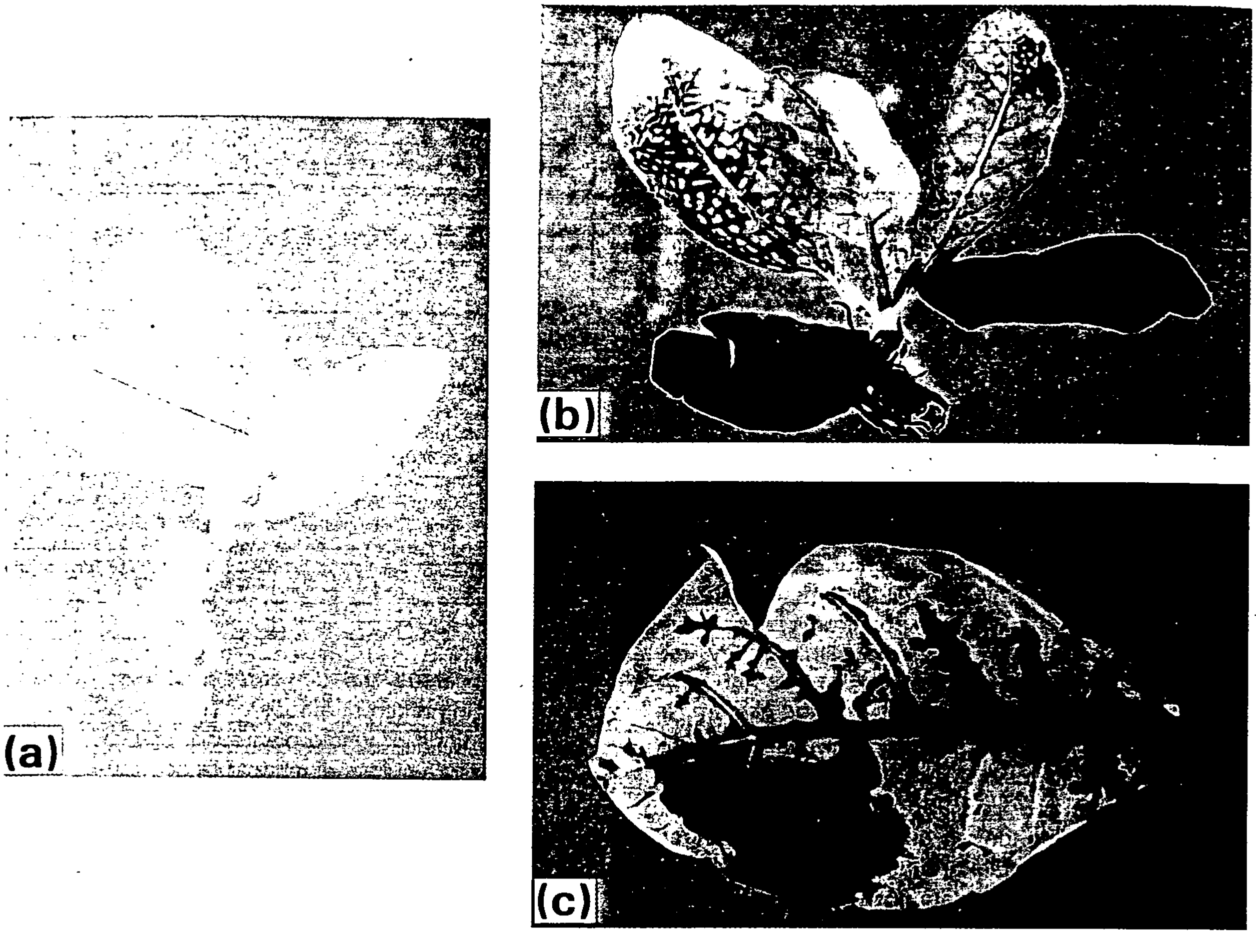

Figure 3. Localization of GUS enzyme activity after growing two cuttings of one transgenic plant on 2MS medium (a) which was supplemented with 1 mg l^{-1} Tc (b,c).
The dark blue staining represents high levels of GUS enzyme activity. The part of the leaf in (c) that was stained intensely blue had touched the medium. Plants had been grown on Tc containing medium for 2 weeks.

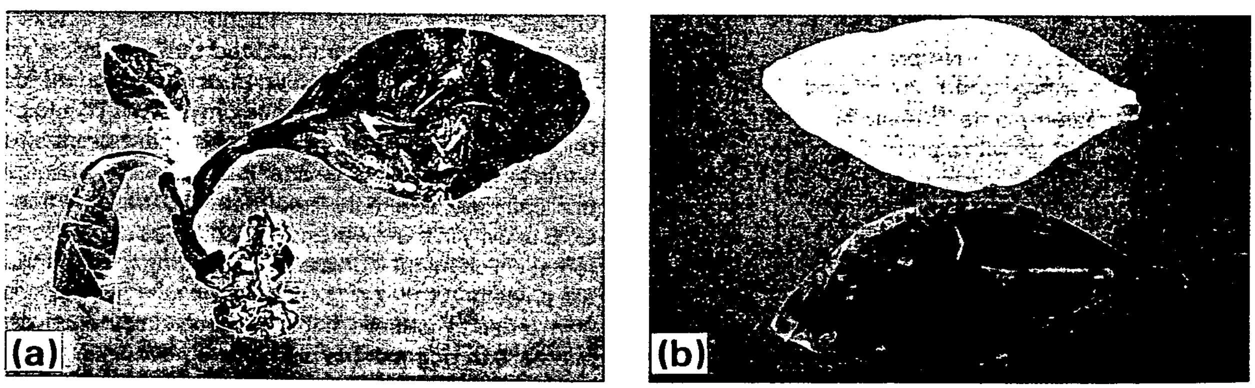

Figure 4. Localization of GUS enzyme activity.
(a) Localization of GUS enzyme activity after growing plantlets on vermiculite with Tc containing Hoagland buffer for 2 weeks. To enhance transpiration, the lid of the tissue culture container was removed under the hood for 15 min once a day. Every 3 days, Hoagland buffer containing fresh Tc was added.
(b) Direct comparison of an uninduced leaf with a leaf detached from the plant shown in (a).

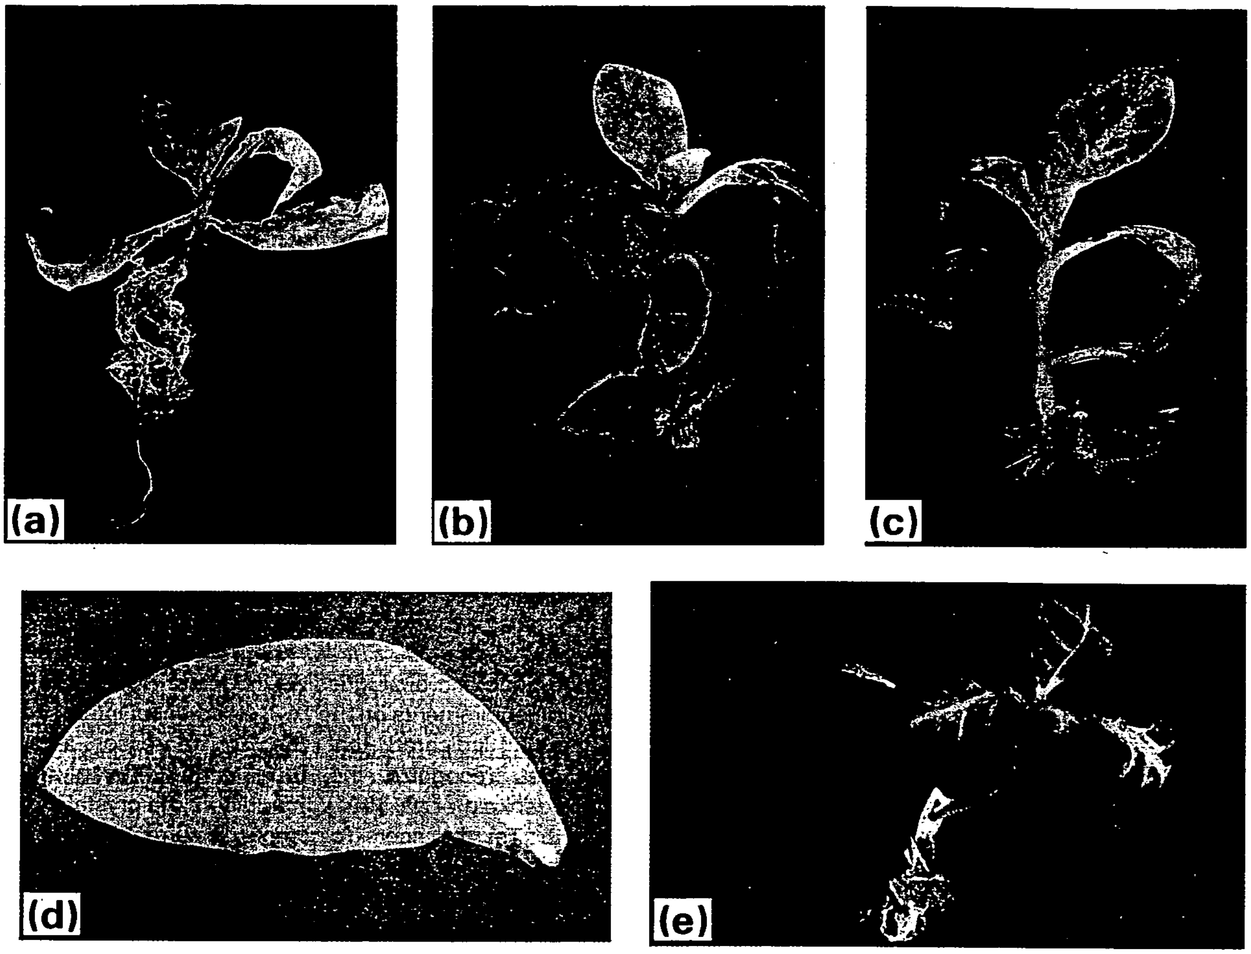

Figure 5. Localization of GUS enzyme activity after growing plantlets on vermiculite with Hoagland buffer.
Plantlets shown in (b) and (e) were submersed in a Tc containing buffer (1 mg l^{-1}) for 15 min once a day for 2 weeks. Plant in (a) is an independent cutting of the plant in (b), but grown on 2MS without Tc. The leaf shown in (d) is from an independent cutting of the plant in (e) that had been kept on 2MS without Tc. The plant in (c) was transformed with a chimeric wild-type CaMV 35S promoter–GUS construct.

tion in the growth chamber. As a second improvement we grew the plants on moist vermiculite, which had the advantage that fresh Tc could be added without cutting off the roots. As shown in Figure 4, homogeneous staining was observed throughout the plant, indicating sufficient distribution of the antibiotic. As determined by the fluorimetric GUS assay the gene was induced 500-fold under these conditions. This indicated that the 50-fold induction that had been measured 2 days after infiltration of single leaves might have been an underestimation because maximal levels of protein are not reached under these conditions.

As a third way of induction under tissue culture conditions we put whole plantlets into a breaker containing a buffer with 1 mg l^{-1} Tc. This type of Tc application also led to a GUS staining pattern that was indistinguishable from that of tobacco plants transformed with the wild-type 35S promoter fused to the GUS gene (Figure 5). Thus the light blue staining in the upper leaf is a property of the CaMV 35S promoter and not due to limited Tc uptake in younger leaves. In the long run, however, this mode of Tc application leads to some browning of the stem and the roots, so that we consider uptake through the roots as described above as more useful. Again, in this experiment, 500-fold induction at the level of GUS activity was observed.

In plants grown under greenhouse conditions, the promoter was de-repressed by applying the antibiotic through the roots (Figure 6). Plants suffered when sprayed with Tc in the presence of Saprogenate and uptake was poor when Saprogenate was omitted (data not shown).

Kinetics of de-repression and re-repression of the promoter

We have followed the kinetics of de-repression by taking samples from a Tc-treated plant and assaying them for

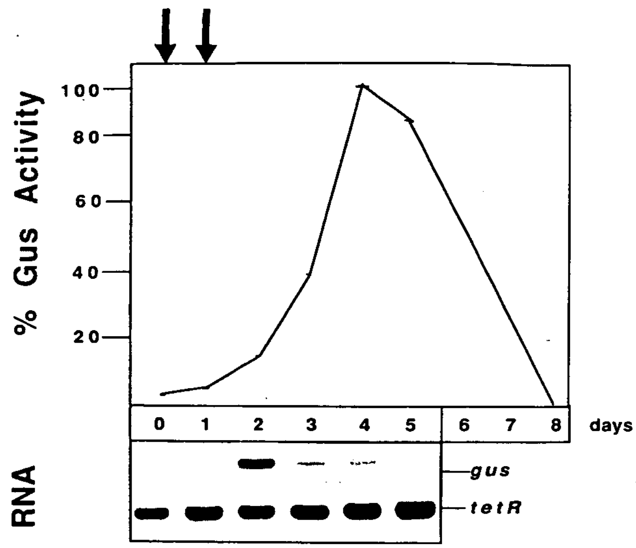

Figure 6. Time course of de-repression after Tc uptake through the roots in plants adapted to greenhouse conditions.
Arrows point to the 2 days where fresh Tc was added (1 mg l^{-1}). Each day a leaf was harvested for analysis of GUS enzyme activity and mRNA abundance.

GUS activity and RNA expression (Figure 6). As Tc uptake through roots had turned out to be the best way for de-repression of the promoter we used the following set-up for Tc treatment under greenhouse conditions. One of the transgenic plants, which contained six leaves at day 0, was cultivated with its roots hanging down into a beaker containing Hoagland buffer with fresh air being supplied through an aquarium pump. On day 0, Tc was added at a concentration of 1 mg l^{-1}, and the medium was exchanged only once on day 1 by a fresh batch of buffer, again containing 1 mg l^{-1} Tc. Each day a whole leaf was harvested for analysis of GUS activity and RNA extraction. Whereas maximal amounts of RNA were already detected on day 2, maximal levels of GUS enzyme activity (40-fold de-repression in this experiment) were observed on day 4. As long as detectable amounts of GUS RNA were present GUS activity continued to accumulate. We cannot clearly state at this moment if this—with respect to the RNA—delayed accumulation of the gene product is typical for the GUS reporter system or if it is caused by the untranslated leader, which contains at its 5′ end an almost complete palindromic operater sequence (Figure 1a). The kinetics of appearance of a gene product has to be specifically determined for each individual gene product, whereas RNA induction can be assumed to be maximal within a few days after addition of the antibiotic.

The antibiotic seems to become inactivated rather quickly in the plant because 2 days after the last addition of fresh Tc mRNA levels started to decrease and were indistinguishable from background levels after 4 days. This could be due to the light sensitivity of the antibiotic, because we do not see this effect when we incubate Tc treated leaves in the dark (Gatz *et al.*, 1991). One week after the last treatment with Tc, no GUS activity was detectable. This feature is extremely useful for the transient expression of a transgene, but for continuous de-repression fresh Tc has to be added at least every other day.

In conclusion, we have constructed a tightly repressed plant promoter that can be de-repressed with very low amounts of Tc. Using GUS as a reporter system we have demonstrated that homogeneous de-repression can be achieved by Tc uptake through the roots or through leaves. In terms of repression efficiency and de-repressibility the system seems to be suitable for the controlled expression of any transgene. It remains to be investigated, however, if plants carrying genes, which are lethal when expressed, can be regenerated using this system. Though Tc is applied at concentrations where we did not observe any phenotypic effect or a reduction of expression of the *S4* gene or the *tetR* gene under the control of the CaMV 35S promoter (Gatz *et al.*, 1991), we are going to develop non-antibiotic analogues as inducers. Studies on structural requirements on the Tc–Tet repressor interaction has already indicated that the Tet repressor and ribosomes recognize the drug in a different manner (Degenkolb *et al.*, 1991). In addition, the crystal structure of the Tet repressor –Tc complex is currently being solved (Parge *et al.*, 1984) so that detailed information on the synthesis of a non-antibiotic inducer should be available in the near future (W. Hillen, personal communication).

Experimental procedures

Plants, bacterial strains and media

Nicotiana tabacum L. was obtained through 'Vereinigte Saatzuchten' (Ebstorf, Germany). Plants in tissue culture were grown under a 16 h light/8 h dark regime on Murashige and Skoog medium (Murashige and Skoog, 1962) containing 2% sucrose (2MS) or on vemiculite with Hoagland buffer. *Escherichia coli* strains DH5α (Bethesda Research Laboratories, Gaithersburg, USA) and WH207/pRT241 (Wissmann *et al.*, 1986) were cultivated using standard techniques (Sambrook *et al.*, 1989). *Agrobacterium tumefaciens* strain C58C1 containing pGV2260 (Debleare *et al.*, 1984) was cultivated in YEB medium (Vervliet *et al.*, 1975).

Reagents

DNA restriction and modification enzymes were obtained from Boehringer Mannheim (Ingelheim, Germany) and New England Biolabs (Danvers, USA). Synthetic oligonucleotides were synthesized on an Applied Biosystems (Foster City, USA) DNA synthesizer (380A). Chemicals were obtained through Sigma Chemical Co. (St Louis, USA) or Merck (Darmstadt, Germany).

Recombinant DNA techniques

Standard procedures were used for recombinant DNA work (Sambrook *et al.*, 1989).

Constructs

First an oligonucleotide containing a *Spe*I- (−53), a *Sna*bI (−32), a *Stu*I- (−22), a *Xba*I (−16), a *Xho*I-(−3) and a *Bgl*II- (+2) site was insert d between the *Hga*I-site(−55) and the *Bgl*II site (+2) of pTET7 yielding pIGF107 using the same strategy as described previously (Gatz and Quail, 1988). Two complementary oligonucleotides with cohesive *Spe*I and *Bgl*II sites were synthesized: (oligonucleotide 1: CTAG-ACTCTATCAGTGATAGAGT-G-TATATAA-G-ACTCTATCAGTGATAGAGT-GA-ACTCTATCAGT GATACAGT-TAACGGTACCT, oligonucleotide 2: CTAGAGGTA CCGTTA-ACTCTATCACTGATAGAGT-TC-ACTCTATCACTGA TAGAGT-C-TTATATA-C-ACTCTATCACTGATAGAGT). This synthetic DNA fragment, which contained three operators, the CaMV 35S TATA-box as well as an *Hpa*I and an *Asp*718 site downstream of the third operator was inserted into pIGF107, cut with *Spe*I and *Xba*I, yielding pTriple-Op-Cat. Recombinant clones were detected using the repressor titration system described by Wissmann *et al.* (1986). This modified promoter was cloned as a *Sma*I–*Xba*I fragment in front of the GUS gene, using pAT3. The promoter in pAT3 was excised as an *Asp*718–*Xba*I fragment and was replaced by the 'Triple-Op'-promoter fragment after filling in the *Asp*718 site of pAT3. pAT3, which is a binary vector containing a hygromycin resistance gene, was used to transform a *tetR*$^+$ transgenic plant via *Agrobacterium tumefaciens* mediated gene transfer (Rosahl *et al.*, 1987).

Binding studies with purified Tet repressor

The 'Triple-Op'-promoter was excised as an *Eco*RI/*Bgl*II-fragment, purified from vector DNA using the 'Gene Clean' kit from Dianova (Hamburg) and end-labelled by filling in the protruding ends in the presence of [α-^{32}P]dATP using Klenow polymerase. Binding reaction and gel electrophoresis were carried out as described previously (Gatz *et al.*, 1991).

Transient expression in tobacco protoplasts

Isolation, transformation and chloramphenicol acetyl transferase assays were essentially as described by Frohberg *et al.* (1991).

Northern blot analysis

Total RNA from leaves was prepared according to Logemann *et al.* (1987). Poly(A)$^+$ RNA was prepared using the 'Dynabeads mRNA Purification Kit' from Dynal (Hamburg). Blotting and hybridization were carried out as described previously (Heyer and Gatz, 1991).

Assays for GUS activity

For the fluorometric GUS assay, explants were homogenized and incubated with the substrate 4-methylumbelliferyl-β-D-glucuronide at 37°C. Quantification of the fluorescence was done according to Jefferson (1987) and Jefferson *et al.* (1987). Protein concentrations were determined according to Bradford (1979).

For *in-vivo* staining, intact plant material was vacuum infitrated with 1 mM X-Gluc (5-bromo-4-chloro-3-indolyl-β-D-glucuronic acid cyclohexylammonium) and incubated overnight at 37°C.

Tobacco transformation

Transformation of tobacco plants was carried out using the *Agrobacterium tumefaciens* leaf disc technique as described by Rosahl *et al.* (1987).

Application of tetracyline to the plants

For Tc application under axenic conditions, plants were either grown on 2 MS medium with 1 mg l^{-1} Tc, or on vermiculite in Hoagland buffer 1 mg l^{-1} Tc. Alternatively, plants were submersed once a day for 15 min in 1 mg l^{-1} Tc in 50 mM sodium citrate (pH 5.5). Aerial parts of plants adapted to greenhouse conditions were submersed once a day for 15 min in 1 mg l^{-1} Tc, 0.025% Saprogenate (Hoechst, Frankfurt) in 50 mM sodium citrate (pH 5.5). For Tc uptake through roots, plants were cultivated in a beaker containing Hoagland buffer and 1 mg l^{-1} Tc. Oxygen was supplied through an aquarium pump.

Acknowledgements

We thank Drs W. Hillen and L. Altschmied for purified Tet repressor, Dr Udo Schmitz and Hans-Peter Braun for the *S4* probe isolated from potato and Arnd Heyer for fruitful discussions. Correlation of the expression of the nuclear photosynthetic gene ST-LS1 with the presence of chloroplasts

Jörg Stockhaus, Jeff Schell[1] and Lothar Willmitzer

Institut für Genbiologische Forschung Berlin GmbH, Ihnestrasse 63, D-1000 Berlin, and [1]Max-Planck-Institut für Züchtungsforschung, Egelspfad, D-5000 Köln 30, FRG

Communicated by J.Schell

A detailed analysis of the expression of a chimeric gene, consisting of the upstream region of the nuclear photosynthetic gene ST-LS1, encoding a component of the water-oxidizing complex of photosystem II, fused to the coding sequence of β-glucuronidase (GUS) as a reporter, is described. The expression of this chimeric gene at the cellular level was detected by histochemical methods and shows that the expression of this gene is correlated with the presence of chloroplasts. Interestingly, the GUS activity was not only detected in typical photosynthetic tissues, e.g. leaves and stems, but also in green roots containing chloroplasts. In contrast no activity was detected in neighbouring white root tissue which was devoid of chloroplasts. One can therefore separate the relative importance of the (morphological) differentiation steps responsible for the formation of tissues normally involved in photosynthesis, from the importance of the developmental stage (characterized by the presence of chloroplasts), for the expression of this nuclear photosynthetic gene. Our data strongly suggest that the developmental stage of the plastids is the primary determinant for the activity of this nuclear photosynthetic gene, although they do not yet allow the exclusion of the reverse type of control, i.e. control of the differentiation of the plastid by the expression of certain nuclear genes. A chimeric gene, consisting of the promoter of the 35S cauliflower mosaic virus (CaMV) gene and the GUS coding sequence, was used as a control throughout the experiments, confirming that the observed differential ST-LS1–GUS gene expression reflects the particular transcriptional regulation impacted on this gene by its *cis*-acting regulatory sequences.

Key words: cell-specific expression/chloroplast dependent expression/photosynthetic gene/35S promoter

Introduction

One important feature of eukaryotes is the fact that their genetic information is divided between two or, in the case of higher plants and algae, three different organelles—the nucleus, the mitochondria and the plastids. One important task for the cell is the coordination of the expression of genes present in these different cell compartments. This is of special importance in view of the fact that many plastidic and mitochondrial proteins are encoded by nuclear genes. Yeast mutants which are devoid of mitochondrial DNA, but nevertheless form organelles which structurally resemble mitochondria, are examples for the importance of the nuclear genome.

The photosynthetic apparatus of higher plants consists of several large protein complexes. As these complexes are encoded by both nuclear and plastidic genes, the plant cell therefore is faced with the problem of coordinating the expression of a large number of genes present in both compartments.

The molecular mechanisms which lead to this coordinated expression are unknown. In addition to light irradiation, which triggers the expression of several nuclear photosynthetic genes (Tobin and Silverthorne, 1985), the developmental stage of the cell is also important for their expression. In mature plants these genes are highly expressed in leaf mesophyll cells, whereas under natural growth conditions no expression is detectable in, for example, roots.

Several recent observations indicate that a 'plastidic factor' might be involved in the regulation of nuclear photosynthetic genes. It has been reported by Oelmüller and Mohr (1986) that the photo-oxidative damage of chloroplasts in mustard seedlings grown on a medium containing the herbicide Norfluorazon, leads to a severe reduction of the amount of translatable RNA, encoding the small subunit ribulose biphosphate carboxylase (RBCS) or the chlorophyll a/b binding protein (CAB). After a partial recovery of the chloroplasts, the amount of translatable mRNA increases again (Schuster *et al.*, 1988). Similar effects have been observed for the accumulation of CAB mRNA in carotenoid deficient tissue of maize seedlings where the carotenoid deficiency was due either to a mutation or to treatment with a herbicide (Mayfield and Taylor, 1984). Chlorophyll deficient maize seedlings, however, which contain plastids arrested in a developmental stage prior to chloroplast formation, accumulate normal levels of CAB mRNA (Mayfield and Taylor, 1984).

In the cases described above, the photo-oxidative damage of the chloroplasts did not affect the expression of several genes encoding cytoplasmic proteins (Reiß *et al.*, 1983; Mayfield and Taylor, 1984). These and other observations (Eckes *et al.*, 1985; Simpson *et al.*, 1986; Börner, 1986; Stockhaus *et al.*, 1987a) can be taken as indicative of a so-called 'plastidic factor', produced by the chloroplasts at a certain stage of development and which is essential for the expression of nuclear encoded chloroplastidic proteins. The observations summarized above are, however, hampered by the fact that all these data are based either on the use of inhibitors or of mutants leading to a photo-oxidative damage of the chloroplasts. With these experiments it is difficult to prove that the photo-oxidation will only influence the expression of the photosynthetic genes studied by the different authors and not result in any side effects. Furthermore these data are all based on the analysis of tissue homogenates. An analysis of the expression of these

genes at the single cell level would undoubtedly allow the establishment of a firmer correlation.

In order to overcome these limitations we decided to use an alternative approach which allows us to follow the expression of a well-characterized gene encoding a protein involved in photosynthesis at the single-cell level in intact 'wild-type' plants. Following this approach, we hoped to answer the question whether or not a close correlation of the activity of this gene with the developmental stage of the plastids could be established.

To this end we used β-glucuronidase (GUS) (Jefferson *et al.*, 1987) as a marker enzyme for the analysis of the cell specificity of ST-LS1 gene expression. ST-LS1 is a nuclear gene of potato, which was originally isolated by differential screening of cDNA libraries from leaves. This gene is expressed in a leaf/stem specific manner (Eckes *et al.*, 1985, 1986) and encodes a 10.8 kd protein associated with the oxygen evolving complex of photosystem II (Lautner *et al.*, 1988). For the experiments described below, a 1600 bp long upstream fragment of the ST-LS1 gene containing *cis*-elements sufficient both for high and specific expression of a chloramphenicol acetyltransferase (CAT) gene (Stockhaus *et al.*, 1987b) was fused to the GUS coding sequence. As a positive control we used a construct composed of the cauliflower mosaic virus (CaMV) 35S transcript (35S) promoter and the GUS coding sequence. These chimeric genes were introduced into potato (homologous system) and tobacco (heterologous system). The cell specificity of their expression was analysed in various organs and at various developmental stages at the cellular level. The observed correlation between ST-LS1−GUS gene expression and the presence of chloroplasts is discussed.

Results

Construction of ST-LS1−GUS and 35S−GUS genes and integration into the plant genome

The ST-LS1 gene upstream sequences from position −1600 to +11 (Stockhaus *et al.*, 1987b) were fused to the GUS coding sequence, followed by a polyadenylation signal of the T-DNA gene encoding the nopalinesynthase (abbreviated as ST-LS1−GUS) (see Figure 1A). A chimeric gene, consisting of the 35S promoter from position −526 to +4, GUS coding sequences and a polyadenylation signal derived from the CaMV 35S gene (see Figure 1B) (abbreviated as 35S−GUS) served as a positive control. By using the 35S promoter, we wanted to demonstrate that the absence of staining in some tissues (cf. below) observed for the ST-LS1−GUS construct is not due to artefacts caused by the lack of substrate in these cells, but rather to differential activity of the ST-LS1 promoter.

These constructs were inserted into the binary vector BIN19 (Bevan, 1984) and were used for the transformation of potato and tobacco plants via *Agrobacterium* strain pGV2260. The substrate 5-bromo-4-chloro-3-indolyl-glucuronide (X-Gluc) was used for the histochemical analysis of transgenic plants. This results in a blue staining of cells expressing the GUS enzyme (Jefferson *et al.*, 1987; Jefferson, 1987). In untransformed plants there was no GUS enzyme activity detectable in any of the tissues described here (data not shown). The data described below are based on the analysis of a number of independent transgenic potato and tobacco plants.

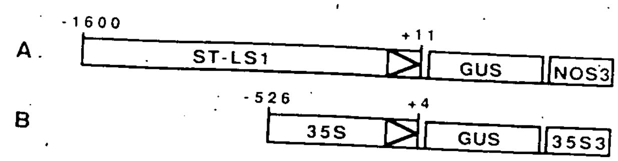

Fig. 1. Representation of the chimeric genes used for the analysis of the cell-specific expression patterns. **(A)** The ST-LS1 upstream sequences from position −1600 to +11 were fused to the GUS coding region and a polyadenylation signal of the nopalinesynthase gene (NOS3). **(B)** A chimeric gene consisting of the 35S upstream sequences from position −526 to +4, the GUS coding sequence (GUS) and the 35S polyadenylation signal (35S3) was used as a positive control.

ST-LS1−GUS and 35S−GUS gene expression in photosynthetic organs

The high level of steady-state ST-LS1 mRNA in leaves (Eckes *et al.*, 1985) indicated that this gene is strongly expressed in this organ. In order to identify the cells expressing the ST-LS1−GUS gene, the staining reaction was performed with transverse potato leaf sections. Very intensive staining of spongy mesophyll, palisade mesophyll and cells associated with the vascular bundles was observed (see Figure 2A). By electron microscopy it was demonstrated that parenchymatic cells which are associated with the vascular tissue contain chloroplasts. Parenchymatic cells of the middle rib of the leaf do not express the ST-LS1−GUS gene and do not contain chloroplasts.

This expression pattern is very similar to the one observed for the 35S−GUS gene which is also expressed to high levels in the palisade and spongy mesophyll cells as well as in parenchymatic cells associated with the vascular tissue (see Figure 2A).

The leaf epidermis is mainly composed of epidermal cells, stomata guard cells and trichomes. This tissue allows the comparison of the expression of the GUS fusions in photosynthetically inactive epidermal cells, containing rudimentary plastids, and photosynthetically active guard cells, which do contain chloroplasts. In contrast to the 35S−GUS gene, which is expressed both in epidermal and in guard cells (see Figure 2C), the ST-LS1−GUS gene expression is restricted to the chloroplast containing guard cells (see Figure 2B). This observation demonstrates that the substrate is not the limiting factor in epidermal cells, but that the staining pattern reflects the differential expression of the ST-LS1−GUS gene. It is furthermore remarkable that in tobacco trichomes both genes are expressed. In the small cells at the trichome tip which contain many chloroplasts the ST-LS1−GUS gene is however expressed to a higher level than the 35S−GUS gene (see Figure 2D and E).

In stem tissue of transgenic ST-LS1−GUS plants we detected low GUS enzyme activities in cells associated with the phloem tissue. In parenchymatic cells of either the pith or the stem-cortex respectively there was no detectable GUS enzyme activity (see Figure 2F). The 35S−GUS gene is highly expressed in parenchymatic cells of the phloem tissue (see Figure 2G). The analysis of longitudinal sections of the shoot apex confirmed the results obtained with the cross-sections. The ST-LS1−GUS gene expression is restricted mainly to the axillary buds and to parts of the apical meristem (see Figure 2H), whereas the 35S−GUS construct is highly expressed in the vascular tissue, axillary buds and in certain cells of the apical meristem (see Figure 2I).

Dark-field photographs of transverse stem sections of a ST-LS1–GUS plant (**F**) and a 35S–GUS plant (**G**); longitudinal sections of the shoot apex of a ST-LS1–GUS plant (**H**) and a 35S–GUS plant (**I**). a, axillary bud; am, apical meristem; c, cortex parenchyma; e, epidermal cell; g, guard cell; p, pith parenchyma; ph, phloem; pp, palisade parenchyma; sp, spongy parenchyma; tr, trichomes; v, vascular tissue; x, xylem.

Expression pattern in non-photosynthetic organs, e.g. roots and tubers of transgenic potato plants

In a second series of experiments we analysed the expression of the GUS fusions in organs characterized by the lack of chloroplasts under normal growth conditions.

The histochemical analysis of potato tuber cross-sections demonstrates that the ST-LS1–GUS gene is not expressed in tubers under normal growth conditions. In tubers exposed to white light for a few days, however, weak ST-LS1–GUS gene expression is detectable in rudimentary leaves of sprouting green buds (see Figure 3A) and the outer layer of chloroplast containing parenchymatic cortex cells (see Figure 3C). The 35S–GUS gene is expressed in parenchymatic cells associated with the vascular tissue in the pith (see Figure 3D) and in germinating buds (see Figure 3B). There was no expression detectable in the starch containing parenchymatic cells in the pith and in the periderm tissue of the tuber. Using transversal sections of roots of transgenic potato plants grown in soil we detected no ST-LS1–GUS gene expression (see Figure 3E), whereas the 35S–GUS

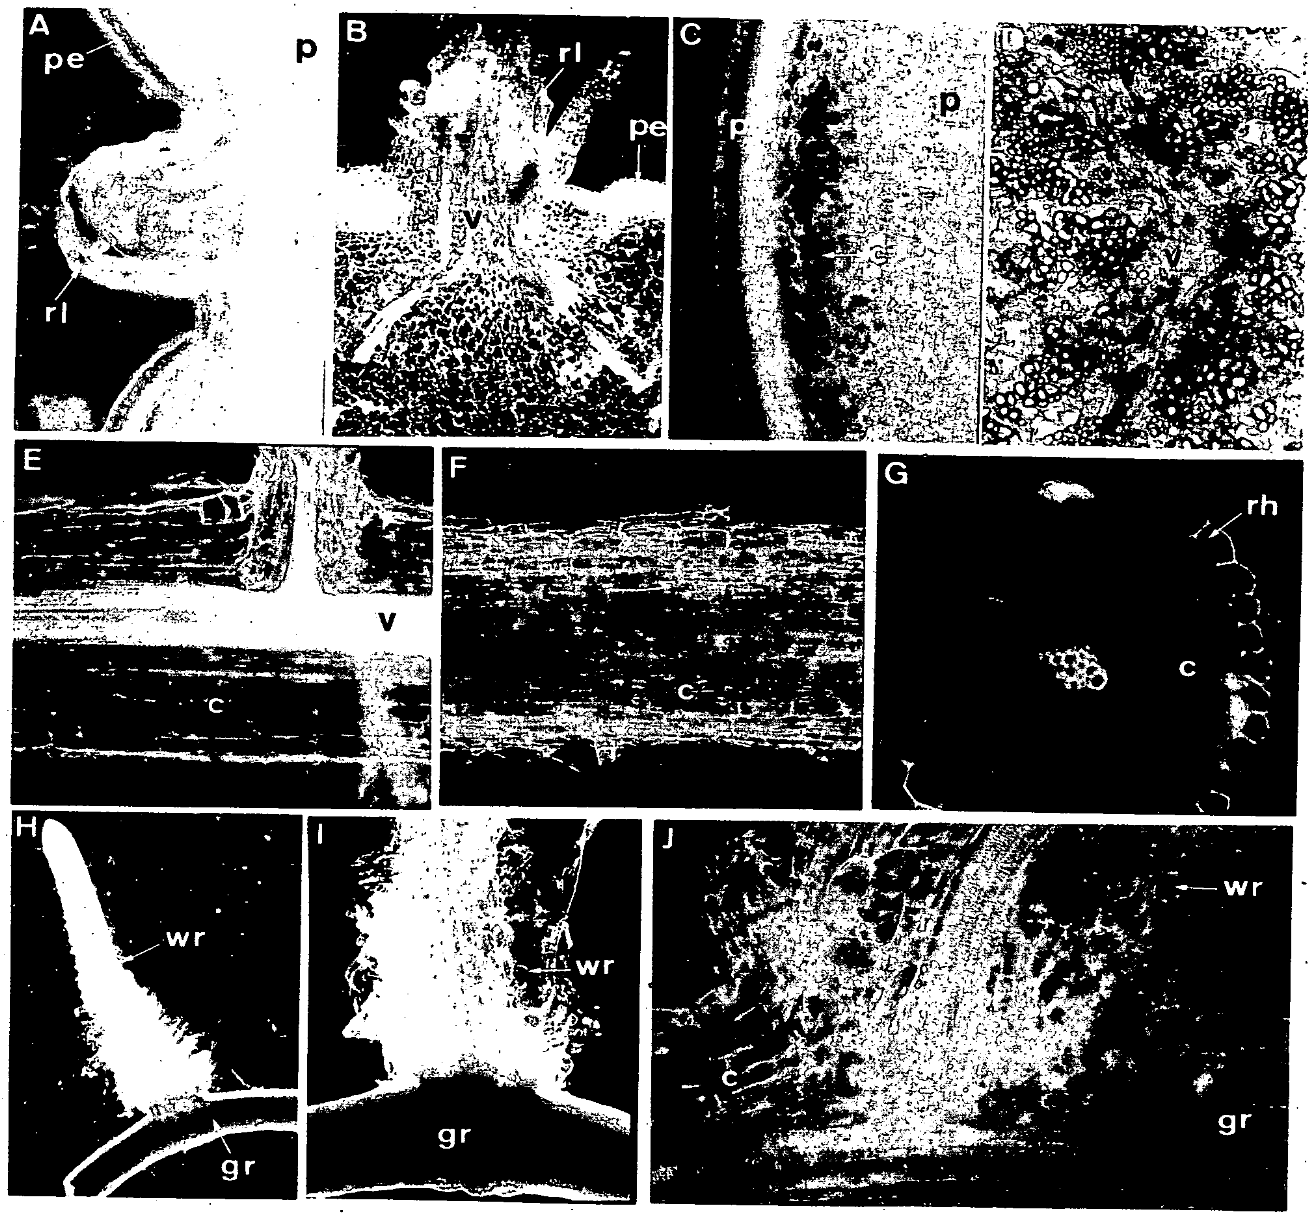

Fig. 3. Histochemical localization of GUS enzyme activity in roots and tubers of potato plants transformed with the ST-LS1−GUS or the 35S−GUS gene. Dark-field photographs of transverse sections of tubers of ST-LS1−GUS plants (**A**,**C**) and tubers of 35S−GUS plants (**B**,**D**); longitudinal section of a root of a ST-LS1−GUS plant grown in soil (**E**) and a 35S−GUS plant grown in soil (**F**); fluorescence photograph of a cross-section of a root of a potato plant grown in tissue culture (**G**). Dark-field photograph of an intact root of a tissue culture ST-LS1−GUS plant before (**H**) and after the GUS reaction (**I**); longitudinal section of a root of a ST-LS1−GUS plant grown in tissue culture (**J**). c, cortex parenchyma; gr, green root; p, pith parenchyma; pe, periderm; rh, rhizodermis; rl, rudimentary leaves; v, vascular tissue; wr, white root.

gene is highly expressed in the parenchymatic tissue of the root (see Figure 3F).

Roots of potato plants grown in tissue culture and which are therefore exposed to light do contain chloroplasts in parenchymatic cells (Eckes *et al.*, 1985) (see Figure 3G). The redifferentiation of these parenchymatic cells to chloroplast containing cells starts at a certain distance from the root tip. White side roots, growing out of older green roots (see Figure 3H), therefore represent a unique system allowing a direct comparison between ST-LS1−GUS gene expression in green roots, which contain chloroplasts, and young whitish roots which do not.

In parenchymatic cells containing chloroplasts a strong GUS enzyme activity is detectable (see Figure 3J), whereas there is no GUS enzyme activity detectable in the young outgrowing roots (see Figure 3I and J). In whitish roots of tobacco plants grown in tissue culture exposed to white light, we also observed chloroplasts by fluorescence microscopy, though their number is much lower. In these tobacco roots the ST-LS1−GUS gene is expressed, albeit at a rather low level (data not shown). In contrast to this highly differential expression of the ST-LS1−GUS gene in correlation to the

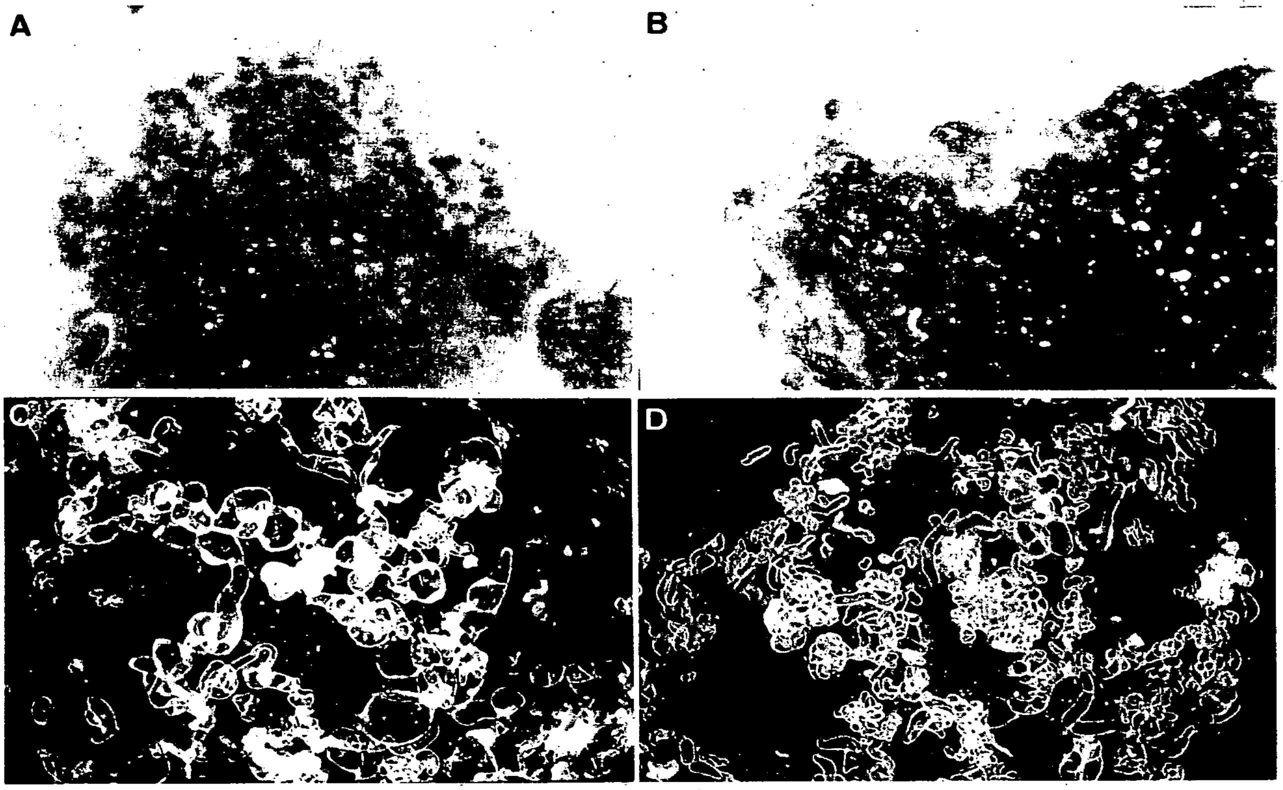

Fig. 4. Histochemical analysis of GUS enzyme activity in callus and suspension culture cells derived from potato plants transformed with the ST-LS1–GUS or the 35S–GUS gene. Bright-field photograph of a ST-LS1–GUS callus (**A**) and 35S–GUS callus (**B**). Dark-field photograph of ST-LS1–GUS suspension culture cells (**C**) and 35S–GUS suspension culture cells (**D**).

presence of chloroplasts, the 35S–GUS gene is expressed in white as well as in green parenchymatic root cells (data not shown).

Expression in potato callus and suspension culture cells

As a final step in our analysis, the expression pattern of both genes in undifferentiated callus and suspension culture cells was determined. A weak expression of the ST-LS1–GUS gene was detected in green callus cells (see Figure 4A). In callus cells representing a different developmental stage characterized by the lack of chloroplasts, no GUS activity was detected. The callus used for these experiments was derived from transgenic potato plants displaying high levels of GUS activity in leaves. The 35S–GUS gene is expressed to much higher levels in callus cells (see Figure 4B).

In tobacco as well as potato suspension culture cells grown under heterotrophic conditions and devoid of chloroplasts we again did not detect any ST-LS1–GUS gene expression (see Figure 4C). This contrasts with the high expression of the 35S–GUS gene in these cells (see Figure 4D).

Discussion

The photosynthetic apparatus localized in the chloroplasts of higher plants contains protein complexes which are encoded by the nuclear and the plastidic genome. In view of the central importance of the photosynthetic activity for the survival of the plant, it is obvious that the expression of the genes of both compartments must be interlinked and tightly controlled. Whereas post-transcriptional control appears to be especially important for the regulation of a number of plastidic genes (reviewed by Gruissem, 1989), the expression of nuclear photosynthetic genes appears to be regulated primarily at the transcriptional level. Light signal transducing systems in which phytochrome is involved play an essential role in this regulation (Tobin and Silverthorne, 1985). The coordinated expression of both nuclear and plastidic genes has, however, received less attention.

The data described in the Results point to a very strong correlation between the expression of a defined nuclear gene from potato (called ST-LS1), encoding a component of the water oxidizing complex of photosystem II, and the presence of chloroplasts. The three most striking examples for the correlation of the presence of chloroplasts with the expression of this nuclear photosynthetic gene are the data obtained for the leaf epidermis, root tissue and the potato tuber. In the epidermis of leaves, the ST-LS1–GUS gene is expressed in guard cells and trichomes which contain chloroplasts, whereas in epidermal cells which are devoid of chloroplasts there was no detectable ST-LS1–GUS gene expression. This result also indicates that, irrespective of the nature of the signal which is responsible for the induction of the ST-LS1 gene, it most likely has to be created within the cell itself and does not have any dominant influence on neighbouring cells. This signal therefore is unlikely to be able to diffuse or to be transported to other cells.

Our observation that the ST-LS1−GUS gene can be expressed in parenchymatic root and tuber cells, provided these tissues are made to contain green chloroplasts, represents an important finding with respect to the relative importance of the morphological differentiation of cells and the developmental stage of the plastids with regard to expression of the ST-LS1 gene. The observation that the ST-LS1−GUS gene is actively expressed in root and tuber cells containing chloroplasts whereas it is not expressed in neighbouring cells of the same type which are devoid of chloroplasts suggests that the presence of chloroplasts might be a prerequisite for the expression of the gene concerned. It should, however, be mentioned that they would also be compatible with an inverse type of control, i.e. control of the differentiation of the plastid by the expression of certain nuclear genes. These results also demonstrate that light—another factor often connected with the expression of photosynthetic nuclear genes—while essential, is not sufficient for induction of ST-LS1 gene expression. All further data described in the Results are in agreement with the main conclusion described above, i.e. the importance of the presence of chloroplasts for expression of the ST-LS1 gene. This result was obtained from the analysis in the homologous system (potato) as well as in the heterologous system (tobacco) for all tissues analysed.

The approach used in this study, i.e. the histochemical detection of β-glucuronidase activity from a chimeric gene transcriptionally driven by the promoter region of the ST-LS1 gene, was used for several reasons.

Firstly we wanted to know whether or not the postulated plastidary signal acts at the level of transcription. The chimeric gene used as a reporter consisted of regulatory sequences derived from a photosynthetic gene and of a coding sequence derived from a prokaryotic gene. We assumed that a prokaryotic mRNA would not be influenced markedly by plant specific post-transcriptional regulation mechanisms.

As outlined in the Introduction the importance of a plastidic factor for the expression of nuclear photosynthetic genes has been implied by several studies. These studies relied on the oxidative damage of chloroplasts by either the use of inhibitors of carotenoid biosynthesis or on the analysis of albino mutants. These previous data cannot with certainty exclude the possibility that the suppression of the activity of photosynthetic genes is due to a non-specific side effect of photo-oxidative damage. Our data, in contrast, were obtained in a 'wild-type' situation and in addition allowed us to monitor the expression on the cellular level.

It is important to examine whether or not the observed differential expression of the GUS enzyme is exclusively due to the specificity impacted by the ST-LS1 promoter. The expression of a chimeric 35S−GUS gene was therefore analysed in parallel and the expression patterns obtained for both genes were compared. This kind of analysis showed that the observed differential expression of the GUS gene results from ST-LS1 promoter activity and not, for example, from accessibility of the substrate or differences of GUS mRNA and protein stability.

Two other reports have to some extent described in a similar way the correlation between expression of another photosynthetic gene and the presence of chloroplasts. Using immunocytochemical methods, Aoyagi *et al.* (1988) showed that a chimeric gene consisting of the promoter of the nuclear photosynthetic small subunit RBCS gene fused to the coding sequence of the CAT gene was expressed in leaf and stem cells containing chloroplasts. A similar result was obtained by Jefferson *et al.* (1987) who demonstrated that treatment of stems with strong white light led to the formation of many chloroplasts in cortical parenchyma cells (chlorenchyma) and led to an increased level of expression of a chimeric gene consisting of a RBCS gene promoter fused to the GUS coding sequence. In these two cases the expression of the respective photosynthetic gene could not be separated from the formation of the typical photosynthetic tissues (leaves and stem). Nevertheless the observation that the *cis*-acting regulatory elements of different photosynthetic genes apparently led to the same kind of expression pattern as described for the ST-LS1 gene suggests that the hypothesized control of the expression of the ST-LS1 gene by the chloroplast could be a general phenomenon and might be relevant for a number of nuclear photosynthetic genes. The identification of tissues which, except for the difference of the developmental stage of their plastids, are very similar (tissue of green and white roots for example) will be very useful for the characterization of the signal(s) controlling the activity of nuclear photosynthetic genes.

Materials and methods

Recombinant DNA techniques

Standard procedures were used for recombinant DNA work (Maniatis *et al.*, 1982).

Transformation of tobacco and potato plants and tissue culture techniques

The chimeric genes were inserted in the vector BIN19 (Bevan, 1984) and introduced into the *Agrobacterium tumefaciens* strain pGV2260 (Deblaere *et al.*, 1985) by direct transformation according to Höfgen and Willmitzer (1988). In order to transfer the chimeric genes to tobacco cells, leaf discs of *Nicotiana tabacum* cv. SNN were infected with the respective *Agrobacterium* strain and subsequently regenerated (Horsch *et al.*, 1985). The transformation and regeneration of *Solanum tuberosum* cv. Desiree plants was performed as described by Rocha-Sosa *et al.* (1989).

Potato and tobacco callus was cultivated on MS medium (Murashige and Skoog, 1962) supplemented with 2% sucrose and 3 mg/l 2,4D (potato) or 1 mg/l 2,4D (tobacco) in a 16 h light/8 h dark rhythm. Suspension cultures were cultivated in liquid MS medium containing 2% sucrose and 1 mg/l 2,4D in continuous dim white light.

Histochemical localization

The histochemical reactions were performed as described by Jefferson (1987) using X-Gluc as substrate. For the sections of plant material a cryo-microtome was used. The staining reactions were performed with either unfixed cuttings or with cuttings fixed for 5−15 min in ice-cold 2% formaldehyde, 1 mM EDTA in 100 mM Na−phosphate (pH 7.0). The fixed cuttings were washed extensively before the staining reaction. The reaction times varied between 2 and 16 h.

Acknowledgements

We thank Carola Recknagel and Carola Mielchen for the tissue culture work and Regina Breitfeld and Beate Küsgen for taking care of the greenhouse plants. We are grateful to Richard Jefferson for providing the GUS coding region, to Reinhard Töpfer for the gift of the plasmid pRT102 and to Meike Köster for providing the plasmid pGUS. This work was supported by a grant from the Bundesministerium für Forschung und Technologie (BCT 0389: Molekulare und Zellbiologische Untersuchungen an höheren Pflanzen und Pilzen).

Mini review

Chemical regulation of transgene expression in plants

E. R. Ward, J. A. Ryals and B. J. Miflin [1]*
Molecular Genetics Department, Agricultural Biotechnology Research Unit, Ciba-Geigy Corporation, P.O. Box 12257, Research Triangle Park, NC 27709, USA; [1] Research and Development, Seeds Division, Ciba-Geigy Limited, CH-4002 Basel, Switzerland (author for correspondence)*

Transgenic analysis has reached an advanced state in plants. In the ten years since transformation with a chimeric selectable marker was reported, the basic tools required to insert and express foreign genes have been developed. However, plant genetic engineers still lack important tools that are common in other systems; one that has only recently emerged is the ability to regulate expression of transgenes with exogenous chemical agents. This review will briefly cover the expanding literature on control of foreign gene expression in plants by application of synthetic compounds.

The goal of chemical gene induction systems is to provide the ability to manipulate levels of gene expression in order to understand better the functions of individual genes, and to facilitate the production of large amounts of a specific gene product. The basic concept underlying such schemes is isolation of a *cis*-acting sequence that operates as the key regulator of a gene with which it is naturally associated, followed by attaching the *cis*-acting element to a gene of interest. This results in expression of the engineered gene in a fashion similar to the natural, chemically regulated gene.

In other well-studied biological systems, the ability to alter gene expression by simple manipulation of the growth medium or addition of a chemical has found widespread use. Common systems include the lac operon in *Escherichia coli* [1], the *GAL 1, 4, 10* regulon in yeast [2], and the glucocorticoid receptor/response element in mammalian cells [3]. An important commercial use for chemical gene regulation is the production of recombinant proteins in fermentation settings (see e.g. [4]). Chemical control also provides the ability to study effects of ectopic expression of a specific promoter, spectacularly demonstrated in the 'super mouse' that arose from fusion of the metallothionein promoter to a rat growth hormone gene [5]. Thus, external regulation of gene expression serves the needs of both applied and basic science.

Combinations of *cis*-acting regulatory sequence and exogenous chemical regulator have been difficult to find in plants. An optimal combination of chemical inducer and target gene results in a tightly regulated system with very low uninduced expression that increases rapidly to high levels upon application of the inducer. The metabolic principles that underlie chemical gene regulation in microbes do not readily extrapolate to plants. For instance, simple inducers of catabolic processes (such as mono- and disaccharides) which are so useful in microbial systems are relatively useless in photoautotrophic organisms. Moreover, the possibilities of regulating the environment of auxotrophs in the field are much more limited than in fermentation systems. Transfer to special growth conditions for the sole purpose of gene induction will not be generally useful in agricultural settings, where conditions are optimized to maximize plant yield. Starvation for a particular nutrient or treatment with a chemical that produces phytotoxicity will be acceptable only in special situations. Natural plant metabolic signals and derivatives thereof are likely to be very

useful for regulating foreign gene expression; unfortunately, only a few such compounds and their target genes have been elucidated. Given the paucity of known natural regulators of plant gene expression, synthetic compounds have to date been more effectively used.

Two basic classes of chemical gene regulation can be distinguished: endogenous systems, which use regulatory signals from plant genes that respond to synthetic chemical treatment, and exogenous systems, which rely on elements from genes from other kingdoms, coupled with chemicals that have no effect on expression of native plant genes. Endogenous regulatory sequences are attractive in that they can be relatively easy to manipulate. For instance, the addition of a 5′ promoter element can be all that is needed to control a foreign coding sequence. On the downside, the use of endogenous plant regulatory sequences means that the native genes that are normally linked to these regulatory sequences are also induced upon addition of the chemical regulator. Thus, it is important to pick not only a potent inducer/regulatory sequence combination, but also an inducer of a class of genes that do not adversely affect the development of the plant. In addition, background levels of gene expression driven by the *cis*-acting sequence must not be overly sensitive to physiological changes in the plant that result from environmental fluctuation or other stresses. The basis for choosing an inducer that fills these criteria is largely empirical, and very few have been tested in intact plants to date. Four possibilities have been documented in the literature, and are reviewed briefly below.

Immunization compounds are chemicals that induce the systemic acquired resistance (SAR) response in plants. SAR is a broad resistance, effective against a variety of pathogens, that is induced by an initial pathogen infection [6] or chemical treatment. The inducing chemicals can be of natural origin, such as salicylic acid, or can be synthetic compounds, such as 2,6,-dichloroisonicotinic acid (INA) [7]. Treatment with a pathogen or an immunization compound induces the expression of at least nine sets of genes in tobacco, the best characterized species [8]. Different numbers and types of genes can be expressed in other plants [9, 10].

The promoter region of one tobacco gene, encoding pathogenesis-related (PR) protein 1a, has been demonstrated to confer chemically-inducible expression on the β-glucuronidase (GUS) reporter gene in laboratory settings [11–13]. We have shown that a PR-1a promoter/GUS fusion in transgenic tobacco behaves in the field as it does in the lab, reaching high expression levels after induction by either salicylic acid or INA (Fig. 1). Moreover, PR-1a promoter has recently been shown to drive chemically inducible expression of the insecticidal CryIA(b) protein of *Bacillus thuringiensis* [14]. This is the only example in the literature of chemical regulation of a potentially important transgenic agricultural trait. Plants expressing *B. thuringiensis* toxin specifically in response to an inducing stimulus may be

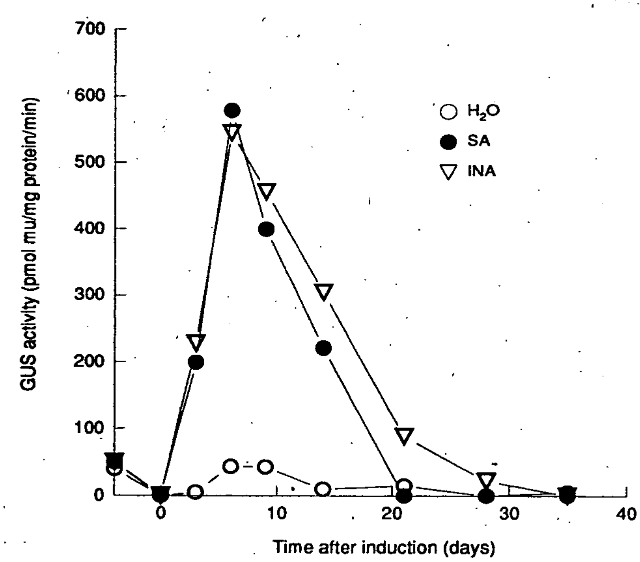

Fig. 1. Field performance of a PR-1a/GUS chimeric gene in transgenic tobacco. Six-week-old plants of a homozygous transgenic line containing a −903 PR-1a promoter fragment fused to GUS [13] were transplanted to the field 7 days before induction. Salicylic acid was applied at 50 mM; INA as a wettable powder formulation consisting of 25% active ingredient at 1 mg/ml. Each point represents the average of duplicate determinations from samples pooled on each day from three replicate field plots. SA, salicylic acid; mu, methylumbelliferone.

advantageous compared to constitutive expressers with respect to resistance management. Population genetic models in which *B. thuringiensis* toxin-resistant alleles are disadvantageous compared to wild-type (sensitive) alleles predict that resistance will spread more slowly when insect populations are given refuge from continual selection for resistance (reviewed in [15]). Thus, the ability to induce expression of the toxin would provide temporal refuge from selection, which should decrease the rate at which a population evolves toward resistance.

The PR-1a promoter/chemical inducer combination is also likely to find basic uses in plant biology. An INA-inducible PR-1 gene has been isolated from *Arabidopsis* (S. Uknes, E.R. Ward and J.A. Ryals, unpubl. data). In this intensively studied genetic model, the ability to control gene expression should be a valuable additional tool for studying the functions of individual genes of interest.

Safeners are chemicals known to induce the expression of enzymes involved in metabolism or detoxification of certain herbicides. The genes induced typically encode glutathione *S*-transferases [16, 17], cytochrome P-450 mixed-function oxygenases [18–20], or other proteins of unknown function. One group has reported the isolation of cDNAs that respond to safener treatment [21]. However, the level of induction for these genes is not as high as that seen for SAR-related genes induced by immunization compounds, which can be induced as much as 10000-fold over background [8, 10] (J.A. Ryals *et al.*, unpubl. data). No reports of chimeric constructions using safener-inducible elements have yet appeared, although such work is presumably in progress.

Genes involved in phenylpropanoid metabolism are known to be inducible by a variety of biotic and abiotic inducers [22]. Lamb and coworkers showed that a bean chalcone synthase promoter fused to the *E. coli uidA* gene in transgenic tobacco was inducible as much as 18-fold by pathogen infection, glucan elicitor from *Phytophthora megasperma*, and $HgCl_2$ [23]. Thus, in principle, regulatory sequences from the phenylpropanoid pathway could be coopted for other uses. Unfortunately, induction of the phenylpropanoid pathway may lead to accumulation of undesirable metabolites that are harmful to normal plant growth [22].

Work from the laboratory of C.A. Ryan over the past twenty years has focused on the wound induction of proteinase inhibitors in tomato and potato [24]. Experiments with transgenic tobacco showed that *cis*-acting sequences of a potato gene could confer wound inducibility on other genes, and that the relevant regulatory signals lay in the 3′ end of the gene [25]. Recently, outstanding progress has been made in elucidating the nature of the chemicals within the plant that signal wound induction systemically. The volatile lipid metabolite methyl jasmonate was found to induce expression of protease inhibitors in several plant species [26]. Despite the basic interest in this discovery, dosage and extent of coverage will probably be difficult to manipulate in systems using volatile compounds for artificial gene control, especially in field settings. More significantly, after an exhaustive search for the *in vivo* systemic inducer of protease inhibitors, an 18 amino acid peptide was found that induces gene expression in amounts as small as a few femtomoles [27]. The discovery of systemin, as this first peptide hormone from plants has been called, opens the door to a previously unexplored area of plant biochemistry. Presumably, expression of other inducible gene systems in plants may also be controlled by exceedingly potent peptides.

Exogenous regulators, which induce genes not occurring naturally in the plant, have the attractive feature of inducing only the introduced transgene. Unfortunately, adapting a gene control system from another organism means overcoming the formidable hurdles of ‘chemodynamics’. Specifically, the inducing compound must be (1) taken up efficiently by the plant, (2) moved systemically to the site of action, and (3) left in an active form by metabolic pathways that degrade or conjugate xenobiotics [28].

Schena *et al.* [29] recently showed that the mouse mammary tumor virus glucocorticoid receptor could confer inducibility on a truncated 35S promoter linked to several tandem copies of

the glucocorticoid response element in protoplasts. These experiments were carried out by cotransfection into tobacco protoplasts. The presence of the receptor gene caused dexamethasone-dependent induction of the GRE-driven reporter gene by as much as 150-fold. The absolute level of expression achieved was approximately 1/10 of that seen using a 35S promoter-driven reporter; presumably, higher levels of expression could be achieved by optimizing the conjunction of GRE to plant promoter elements. Similarly, the developmental and tissue specificity of the newly created inducible promoter could be varied by using individual elements from promoters specifically regulated in time or space during plant development. To date, however, the functioning of this otherwise attractive system has not been reported in stably transformed intact plants.

The Tn*10* tet repressor/operator is a prokaryotic control system that has been shown to function in plants [30]. Tobacco plants were first stably transformed with the *tetR* gene under 35S control. These plants expressed tet repressor at a level of ca. 0.01% of total cell protein. These TetR-expressing plants were transformed again, with a GUS reporter gene driven by a 35S promoter into which tet operator sequences had been integrated. Insertion of two tandem *tetO* sequences between the TATA box of the 35S promoter and the start of transcription conferred 50- to 80-fold repressibility on the GUS gene in the presence of tetracycline.

The definition of what constitutes an agricultural trait is changing quickly as genetic engineering of plants approaches its tenth anniversary. Chemical control has the capability to further expand the range of novel compounds that can be manufactured at commercially useful levels in plants. What are some potential uses of this technology?

One example is the use of plants as bioreactors to produce recombinant proteins. Van Montagu and coworkers showed that the neuropeptide Leu-enkephalin could be produced in the seed of transgenic *Arabidopsis* and *Brassica* by means of a translational fusion to a napin-like seed storage protein gene [31]. Conceivably, extremely high levels of such a peptide, in amounts that would draw deleteriously on the plant's N resources, could be synthesized under chemical control, followed quickly by harvest before significant starvation affected the crop.

Another recent example of a novel biosynthetic capacity conferred on plants through genetic engineering is the production of polyhydroxybutyrate [32]. This polyester thermoplastic is synthesized in three steps from acetyl-CoA by the bacterium *Alcaligenes eutrophus*. The first activity in the pathway, 3-ketothiolase, is found in plant cells. Somerville and coworkers introduced bacterial genes for the remaining two steps, each under the control of the 35S promoter, into *Arabidopsis thaliana*, creating two independent transgenic lines. An F1 hybrid of these lines accumulated PHB granules in the cytoplasm, vacuole, and nucleus. Expression of these genes was clearly harmful to the plant, as manifested by reduction in fresh weight between 20 and 45%. Thus, the ability to trigger a massive burst of PHB synthesis just prior to harvest might be an attractive strategy for its high-level production.

The chemical regulation of foreign genes will be especially powerful once homologous gene replacement becomes a routine technique in plant biology. Nearly all plant *cis*-regulatory sequences studied to date are exceedingly complex [33]. As a result, a defined fragment of a promoter linked to a different coding sequence and inserted into the genome in a random location hardly ever functions as well as it does in its native state. Once it becomes possible to swap a novel coding sequence into the milieu of a regulated locus, the foreign sequence will stand a much greater chance of being regulated like the native gene.

The types of traits that have been introduced into plants to date are relatively limited. While many of these traits will function adequately under constitutive expression, others will be useful only if regulated. As the biochemical bases for more complex plant processes are discovered, increasing numbers of transgenes are likely to be created that will be useful only if placed under exogenous control. The existence of easily used, highly controllable chemical gene regulation systems will

further drive the development of useful regulated phenotypes. Thus, the field of chemical induction of gene expression in plants is young indeed, and the traits that can be controlled using this burgeoning technology are limited only by the imaginations of investigators.

Summary

The complete nucleotide sequence (8024 nucleotides) of the circular double-stranded DNA of cauliflower mosaic virus has been established. The DNA molecule is known to possess three discrete single-stranded discontinuities, often referred to as "gaps," two in one strand and one in the other. The sequence data indicate that gap 1, the single discontinuity in the α strand, corresponds to the absence of no more than one or two nucleotides with respect to the complementary β strand. The two discontinuities in the β strand, however, are not authentic gaps since no nucleotides are missing, but are instead regions of sequence overlap: a short sequence (19 residues for gap 2, at least 2 residues for gap 3) at one terminus of each discontinuity, probably the 5′ terminus, is displaced from the double helix by an identical sequence at the other boundary of the discontinuity. Analysis of the distribution of nonsense codons in the DNA sequence is consistent with other evidence that only the α strand is transcribed. The coding region extends around the circular molecule from 4 map units of gap 1, the map origin, to map position 91, and consists of six long open reading frames. Our findings suggest, but do not prove, that the DNA sequence of the open reading frames is colinear with viral protein sequences. The cistron for the viral coat protein, which is probably synthesized in the form of a precursor, has been situated in coding region IV on the basis of its unusual amino acid composition.

Introduction

Cauliflower mosaic virus (CaMV) is the best characterized of the rather small number of plant viruses containing DNA rather than RNA as genetic material (for reviews see Hull, 1979a; Shepherd, 1979). CaMV DNA is double-stranded (Shepherd, Bruening and Wakeman, 1970) and has been estimated to be 7200–8000 bp long (Shepherd and Wakeman, 1971; Hull and Shepherd, 1977; Lebeuri r et al., 1978). Both lin ar and circular mol cules of similar contour l ngth may be found in CaMV DNA preparations (Shepherd and Wakeman, 1971; Russell et al., 1971; Civerolo and Lawson, 1978). Th circular form accounts for more than 90% of the material in fresh preparations and is the infectious entity (Hull and Shepherd, 1977; Volovitch, Drugeon and Yot, 1978); the linear DNA probably arises by adventitious breakage of circular molecules.

An unusual property of CaMV DNA is the existence of short discontinuities ("gaps") at well defined sites in one or the other strand of double-stranded circular molecules (Hull and Howell, 1978; Volovitch et al., 1978). Typically, there are two interruptions in one strand and one in the other (Volovitch et al., 1978; Hull, 1979b). We have chosen to designate gap 1, the single break in the transcribed α strand, as the zero point of our restriction map of circular CaMV DNA (Hohn et al., 1980), as there is evidence that RNA transcription begins near this point (Hull et al., 1979). The two gaps in the complementary β strand, gap 3 and gap 2, are located at 20 and 53 map units, respectively (Figure 2b). The positions of the three gaps are conserved in all CaMV isolates examined to date (Hull, 1979b) with the exception of CM184, which has undergone a small deletion in the region of gap 3 (Hull et al., 1979).

With the development of sophisticated techniques for constructing recombinant DNA molecules there has been a surge of interest in the possible use of DNA plant viruses such as CaMV as vectors for introducing foreign genes into plants. It is evident, however, that much will have to be learned about the molecular biology of these viruses and the way they interact with their hosts before such a plan can be tested. In this paper we report the complete nucleotide sequence of CaMV DNA (isolate Cabb B-S) and discuss those aspects of the sequence which shed light upon the organization of the CaMV genome.

Results and Discussion

Sequence Determination

A large number of Hinf I, Taq I, Mbo II and other double-stranded restriction fragments of CaMV DNA were prepared with ^{32}P-labeled 5′ termini by treatment with polynucleotide kinase in the presence of γ-^{32}P-ATP. After strand separation or secondary restriction to separate the labeled extremities, the sequence of the first 100–150 nucleotides in from each 5′ labeled terminus was determined by the limited chemical cleavage method of Maxam and Gilbert (1977). Enough data were collected to establish an unambiguous sequence for the entire genome, with over 75% of the molecule sequenced in both strands. (Details of this procedure are in Experimental Procedures.)

The complet sequence of CaMV DNA (isolatè Cabb B-S) is shown in Figure 1. Th sequ nce consists of 8024 bas s and numbering b gins with the first dG at the approximate 5′ boundary of gap 1. Only the sequence of the β strand, which has the sam polarity as viral mRNA (see b low), is presented.

Figure 1. Nucleotide Sequence of Circular CaMV DNA (Isolate Cabb B-S)

Only the sequence of the β strand, which has two gaps and the same polarity as viral mRNA, is presented. Numbering begins with the first dG at gap 1. The sequence is written as a continuous chain everywhere complementary to the transcribed α strand in order to facilitate consideration of coding capacity but, in fact, the β strand is broken at gaps 2 and 3 and the extremities of the sequence at each gap are redundant (see text and Figure 6). The asterisk marks a dG residue which may be paired with a modified dC residue in the complementary strand.

Since the CaMV isolate used to establish the sequence has not been cloned, we were prepared to find some sequence variation within the viral DNA population. Rather surprisingly, however, not one clear-cut example of such heterogeneity was detected in the two CaMV DNA preparations used to establish the sequence. Very occasionally, double signals occurred at a given position in a sequence gel, but examination of other gels covering the region in question or its complementary strand generally revealed such signals to be spurious. Thus, although the existence of rare sequence variants affecting a small proportion of the DNA population cannot be ruled out, most of the DNA molecules of Cabb B-S isolate conform to the sequence presented in Figure 1. Restriction analysis of a large number of pBR322-CaMV DNA recombinants has revealed little sequence variation among the clones, a result consistent with this conclusion (Hohn et al., 1980).

The Coding Region

While it is evident that the nucleotide sequence will ultimately tell us much if not all about the properties of the CaMV genome, a straightforward extrapolation from the DNA sequence to the properties of the final gene products, the viral proteins, is rendered difficult by the complexity of mRNA maturation in eucaryotes and our lack of knowledge of the signals governing this process. Nevertheless, analysis of the coding capacity of the nucleotide sequence permits the broad outlines of CaMV genetic organization, if not the details, to be discerned.

Transcription of CaMV DNA is asymmetric. There is agreement that virus-specified RNA present in infected turnip leaves (Hull et al., 1979; Al Ani et al., 1980) or protoplasts (Howell and Hull, 1978) hybridizes exclusively with the α strand of CaMV DNA, that is, the strand containing only one gap. It is reasonable to believe that most or all of these RNA transcripts encode viral proteins. Such a view is in fact borne out by examination of th coding capacity of the nucleotide sequenc . Figure 2a presents an analysis of th distribution of TGA, TAG and TAA t rmination codons in th three possible coding frames of th β strand, the sequ nce having the same polarity as would an

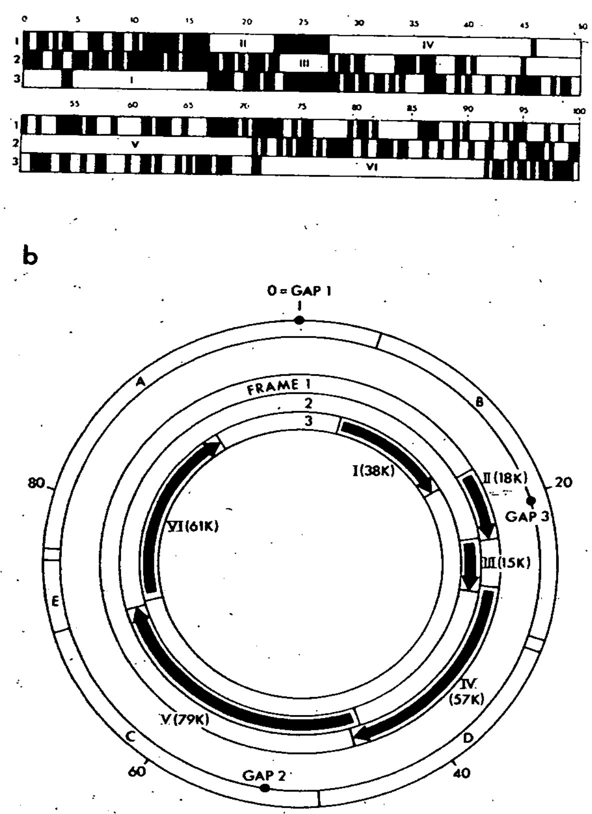

Figure 2a. Distribution of Nonsense Codons in the CaMV β Strand Sequence

Triplet frame 1 begins with the first residue in the sequence as presented in Figure 1, frame 2 with the second nucleotide and frame 3 with the third residue. The sequence in each coding frame was divided into consecutive segments of 12 triplet codons (36 nucleotides). When a nonsense codon occurs in a segment, the corresponding rectangle in the diagram is blackened (▇).

Figure 2b. Distribution of Potential Coding Regions on the Circular CaMV DNA Map

Inner circles give the positions of the six long open reading frames identified in (a) along with the molecular weight in kilodaltons of the longest possible translation product for which each could code (assuming that translation begins with first in-phase ATG initiation codon in each open region). The outer circle gives the positions of Eco RI fragments A–E and the three gaps.

RNA transcript of the α strand. The diagram reveals that, apart from a region of about 1000 nucleotides in the vicinity of gap 1 (91–4 map units), virtually the entire sequence is free of nonsense codons for considerable distances in one or another of the three reading frames. The longest such potential coding sequence, region V, is 2082 nucleotides long. Regions IV and VI are each more than 1500 residues in length, while region I is 1000 nucleotides, region II 500 nucleotides and region III 400 nucleotides long (Table 1). By way of contrast, the sequence complementary to the β strand, a sequence which is not transcribed and hence almost certainly does not code, contains no uninterrupted triplet reading frame of more than 370 nucleotides. It is noteworthy that, with the exception of about 120 nucleotides at the junction between regions IV and V, there is little overlap between successive coding regions. Thus CaMV has not economized its genetic information as has ϕX174 (Sanger et al., 1977) by using different reading frames of the same sequence to specify different proteins.

We are confident that the six long uninterrupted reading frames identified in Figure 2a represent the effective protein coding potential of CaMV DNA. The maximum lengths of the polypeptides for which the six regions may code (assuming translation starts with the first in-phase AUG in each region and that there is no read-through of termination codons) are shown in Figure 2b. Whether any or all of these polypeptides are in fact synthesized in infected tissue is uncertain and will probably remain so until more is known about the manner in which viral RNA transcripts are processed. Evidence is presented below, however, suggesting that a part of region IV encodes the major viral coat protein.

Virus-specific RNA transcripts synthesized in protoplasts prepared from CaMV-infected turnip leaves have been reported to be quite large, with molecular weights in the range of 2×10^6 daltons or greater (Howell and Hull, 1978; Howell, Odell and Dudley, 1979). RNA molecules of this length could accommodate essentially all of the coding portion of the CaMV genome (regions I–VI). Transcripts isolated directly from turnip leaves, on the other hand, were found to be significantly smaller, sedimenting as distinct 18S and 25S species in sucrose gradients (Howell et al., 1979). Howell et al. (1979) have suggested that protoplasts are defective in viral mRNA processing and that the large RNA transcripts which accumulate in this system may be precursors of the smaller molecules. It is uncertain, however, whether this maturation process would involve the joining together (splicing) of discontinuous regions of the mRNA precursor as observed for many eucaryotic mRNAs. Howell et al. (1979) argue that splicing probably occurs, based upon their analysis of hybridization patterns in Southern blots between the radioactive 18S and 25S viral mRNAs and CaMV restriction fragments. In our laboratory, however, electron microscopic examination of specific RNA-DNA heteroduplexes between CaMV DNA and polyadenylated RNA fractions isolated from infected turnip leaves has so far failed to reveal a single instance of single-stranded DNA looping out of such hybrids, as would be expected if the DNA and RNA molecules are not colinear (J. Menissier, personal communication).

Examination of the nucleotide sequence itself provides two, admittedly weak, arguments against extensive involvement of splicing in the mRNA maturation process. First, the canonical splice-junction sequences (5′) $^{A}_{C}$AG↓GTAAGT ... TYTYYYTXCAG↓G (Lerner et al., 1980; Y is a pyrimidine, X is any nucleotide) or close variants thereof are rarely found in the CaMV β strand sequence and then not in places where a splice might be expected, such as across regions where there is a shift in the coding frame. It may be objected, however, that the splice junctions of plants and their viruses may be sufficiently different from those of animals and insects to escape recognition.

A second argument rests upon the way in which the reading frame in the coding region jumps abruptly from one phase to another so that, in all but one case (the junction between regions V and VI), successive open regions overlap slightly or are separated from

Table 1. Coordinates of Possible Coding Regions of CaMV DNA

VI	5713	71.20	7338	91.45	5776	61

[a] Assuming polypeptide chain synthesis starts with the first in-phase AUG in each open region.

one another by only a few nucleotides (Table 1). Thus it is unlikely that the CaMV genome contains noncoding intervening sequences (introns) in the primary coding region (map units 4–91) which are present in primary RNA transcripts but eliminated from mature mRNAs. A splicing pattern of the type observed for adenovirus late mRNAs, however, in which a single nontranslated 5′ leader sequence is spliced to each of several alternate coding sequences (Philipson, 1979), cannot be ruled out from the sequence data alone.

Viral Gene Products

Additional insight into the organization of the CaMV genome could be gained if we could unequivocally equate one or more of the potential coding regions described in the preceding section with a viral gene product. One obvious candidate for consideration is the major viral structural protein. Early investigations of the architecture of CaMV virions were rather confused, with estimations of the number of structural polypeptides present varying from two to seven or more (Tezuka and Taniguchi, 1972; Kelly, Cooper and Walkey, 1974; Brunt et al., 1975; Hull and Shepherd, 1976). The molecular weights of the various polypeptides ranged from 30 to 85 kilodaltons while their molar ratios often depended upon the method of virus purification and the age of the virus preparation. Al Ani, Pfeiffer and Lebeurier (1979), however, have recently shown that the situation is in reality much simpler. They argue that there is only one major CaMV structural protein, a polypeptide of about 42 kilodaltons that we shall refer to as P42. Smaller polypeptides normally associated with virion preparations were shown to have sequences in common with P42 and no doubt arise by proteolytic degradation of the major species, while the polypeptides in the 70–80 kilodalton range are probably artifactual dimers of P42 and its degradation products arising from incomplete reduction of disulfide bonds (Al Ani et al., 1979).

A distinctive feature of CaMV coat protein is its unusually high lysine composition, which amounts to 18% (on a molar basis) of the amino acid content of total virion protein (Brunt et al., 1975). We have examined the coding capacity of each of the six putative coding regions identified in Figure 2 and find that only one, region IV, has the potential to code for a protein approaching this degree of richness in lysine. Figure 3a presents the amino acid sequence corresponding to region IV, beginning with the first ATG initiation codon in the appropriate phase. This hypothetical polypeptide can be seen to have an extremely lysine-rich region n ar the carboxy t rminus (amino acid r sidues 333–410). Table 2 gives the amino acid composition calculat d for a polypeptide spanning this lysine-rich core and having a molecular weight of about 42 kilodaltons. The xact boundaries of the putativ coat protein polyp ptide were chosen to optimize the fit, which is excellent, between the calculated values and those observed for viral coat protein (Brunt et al., 1975), but may be adjusted slightly without affecting the figures significantly. The fit is all the more striking if one takes into account the fact that the amino acid analysis was performed on total virion protein, which no doubt included degradation products of the basic 42 kilodalton polypeptide.

Efforts to elicit synthesis of P42 in cell-free systems primed with mRNA fractions from CaMV-infected leaves have not been successful. Such mRNA fractions do, however, direct synthesis of a virus-specific polypeptide with an estimated molecular weight of about 55 kilodaltons (P55) in a rabbit reticulocyte cell-free system (R. Al Ani and A. Lesot, personal communication). We consider it probable that P55 is the product of total translation of region IV, which could give rise to a polypeptide in this size range (Figure 2b). Viral coat protein, then, would be synthesized in the form of a precursor, thus explaining our failure to obtain mature coat protein in in vitro translation systems. Experiments are under way to discover if there is in fact a serological relationship between in vitro synthesized P55 and viral coat protein.

The lysine-rich core of P42 presumably interacts with the DNA in the intact virion. In this regard, it is noteworthy that the extremities of the longer sequence are extremely rich in glutamic and aspartic acid residues (Figure 3). If the precursor-product relation put forward above for P55 and P42 proves correct, then the supplementary acidic residues in the precursor polypeptide may serve to neutralize the lysine-rich core in the absence of DNA. Processing of the coat protein precursor would, by eliminating the acidic terminal sequences of the longer polypeptide, leave the lysine-rich core of the mature coat protein free to interact with DNA.

The only other CaMV gene product that has been unambiguously identified is a polypeptide of about 62 kilodaltons (P62) which is the most prominent virus-specified translation product primed by polyadenylated mRNA from CaMV-infected leaves (Al Ani et al., 1980). An apparently similar if not identical translation product with an estimated molecular weight of 66 kilodaltons has been described by Howell et al. (1979). P62 can be detected in protein extracted from infected leaves, and cell fractionation experiments indicate that it is associated with the inclusion bodies known as viroplasts (Howell et al., 1979; Al Ani et al., 1980), which accumulate in the cytoplasm of infected cells (for references see Shepherd, 1979). Howell et al. (1979) have used the hybrid-arrested translation (HART) technique (Paterson, Roberts and Kuff, 1977) and cloned Eco RI fragments to show that the greatest part of the sequence encoding their 66 kilodalton polypeptide lies within Eco RI fragment A (map positions 76–5; Figure 2b). Thus open region VI, which is mostly contained within fragment A and has the po-

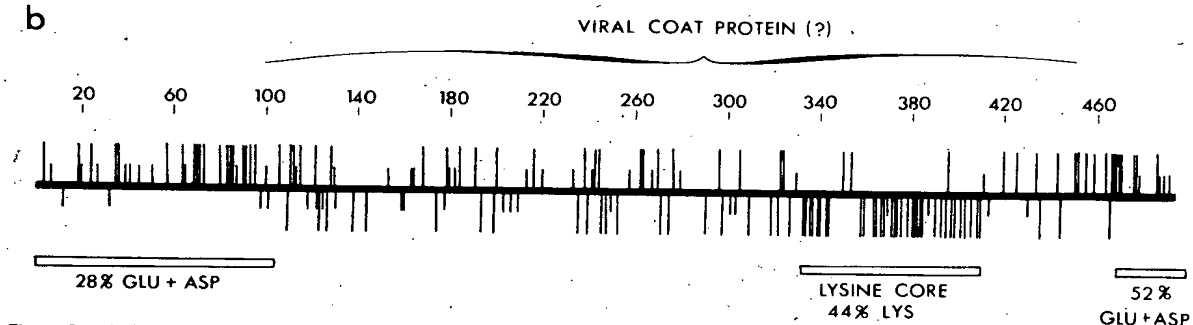

Figure 3a. Amino Acid Sequence Coded for by Open Region IV

The sequence begins with the first in-phase ATG codon (2201–2203) and proceeds to the end of the open region. The two inverted triangles mark the beginning and the end of the portion of the sequence which may correspond to viral coat protein.

Figure 3b. Distribution of Acidic and Basic Amino Acid Residues in the Open Region IV Amino Acid Sequence

Half- and full-length vertical lines pointing upward denote aspartic acid and glutamic acid residues, respectively, while half- and full-length lines pointing downward denote asparagine and lysine.

tential to code for a protein of about the right size, would seem to be the best candidate for the viroplast protein cistron. Al Ani et al. (1980) observed that hybridization of mRNA fractions with both Eco RI fragments A and E inhibits in vitro synthesis of P62, consistent with the aforesaid localization (Figure 2b). The same investigators also found, however, that hybridization with Eco RI fragment B (map units 5–30) also inhibited P62 synthesis, a result not easily reconciled with the sequence data unless splicing is invoked. Reinvestigation of this matter using cloned Eco RI fragments to eliminate the possibility of contamination of fragment B by fragment A appears essential.

The Noncoding Region

The sequence separating the end of coding region VI from the beginning of coding region I does not appear to encode protein. Reading frames 1 and 2 in this portion of the sequence (map units 91–4) are blocked by numerous termination codons (Figure 2). Frame 3 contains a small open region of about 300 nucleotides (map units 0–4) but there is no in-phase ATG initiation codon. The data of Hull et al. (1979) suggest that transcription commences within a few map units downstream of gap 1, the zero point in our sequence, and terminates somewhere between map units 76 and 100. This scheme fits in well with the sequence, as we would expect transcription to begin at or before map position 4.1, the beginning of coding region I (Table 1), and proceed to at least map position 91, the end of coding region VI. About 250 nucleotides downstream from the final triplet in region VI appears the sequence AATAAA (7598–7603), whose RNA equivalent is to be found 15–30 nucleotides prior to the poly(A) tail in a great many eucaryotic mRNAs (Proudfoot and Brownlee, 1976). If this feature is similarly located in CaMV RNA transcripts, then the

termination point for transcription would fall near map position 95.

With regard to initiation of RNA transcription, many eucaryotic mRNA coding genes have AT-rich regions (typically, a variant of the sequence TATAAAA), often flanked by GC-rich sequences, 20–30 nucleotides upstream of the transcription initiation point (for references see Benoist et al., 1980). The CaMV DNA sequence between gap 1 and the beginning of coding region I contains several AT-rich regions but perhaps th most eye-catching example occurs just *before* gap 1: GCCCCCGCTTAAAAAATT (residues 8007–8024). For the present, we reserve judgment on the role, if any, of such sequences in transcription initiation until the 5′ terminus of the initial RNA transcript has been characterized.

Th Gaps

Determination of the sequence in the vicinity of the gaps presented special problems. We have observed, as have Volovitch et al. (1979), that restriction fragments containing a gap often display perturbed behavior during electrophoresis, migrating as a diffuse band or family of bands in the gel. We have also observed that proximity to a gap may render certain restriction enzyme sites refractory to attack. Hohn et al. (1980) have shown that CaMV DNA cloned in pBR322 (no gaps) possesses a Hind III restriction site within 110 nucleotides of gap 3 that was not detected in noncloned DNA. Sequence analysis has shown that the Hind III recognition sequence in fact exists in noncloned viral DNA (positions 1513–1518), but only once were we successful in obtaining cleavage at this site. Several examples of incomplete cleavage at Taq I sites in the vicinity of gaps were also noted.

In spite of these difficulties, a number of short 5′ ^{32}P-labeled double-stranded restriction fragments encompassing each of the three gaps were isolated. When such a fragment was subjected to strand separation, three radioactive single-stranded fragments of disparate length were produced. The two smaller fragments correspond to the two segments of the strand interrupted by the gap while the longest fragment is the continuous complementary strand. Evidently, one of the two shortened single-stranded fragments will have the 5′ terminal nucleotide of the gap at its labeled extremity so that sequence data from this fragment should exactly situate the 5′ limit of the gap with respect to the sequence of the complementary strand. The sequence of the other shortened fragment, which has the restriction site as 5′ terminus and the gap at its 3′ extremity, should in principle define the approximate 3′ limit of the gap, providing that the restriction site is sufficiently close to the gap so that the sequence can be read to its end.

5′ Extremities of the Gaps

Sequence gels for 5′ labeled fragments originating from gaps 1, 2 and 3 are shown in Figure 4. Hull et al. (1979) have identified the 5′ terminal nucleotides of the gaps in CaMV DNA (isolate Cabb B-JI) as dA for gaps 1 and 2 and dG for gap 3. We find the same 5′ termini for the gaps in the DNA of our isolate (Cabb B-S) both upon sequencing gels (Figure 4) or by total P1 nuclease digestion of the 5′ ^{32}P-labeled fragments and electrophoresis of the digestion products at pH 3.5 (data not shown). In numerous experiments, however, the signal corresponding to the second nucleotide from the 5′ labeled end of each gap was always obscured by a heavily labeled diffuse band or pair of bands traversing all four lanes of the sequencing gel (Figure 4). Anomalous signals of this sort were never encountered for ordinary restriction fragments prepared and electrophoresed in parallel, suggesting that an unusual structure or modified nucleotide may be present at these positions in the DNA molecule. The nature of these unusual residues is currently under investigation.

In the course of sequence determination we observed that gap 2 is absent from a portion of the DNA molecules of our preparations. A short Taq I restriction fragment spanning the region of gap 2 was found to migrate as two distinct approximately equimolar components in polyacrylamide gels. Characterization of

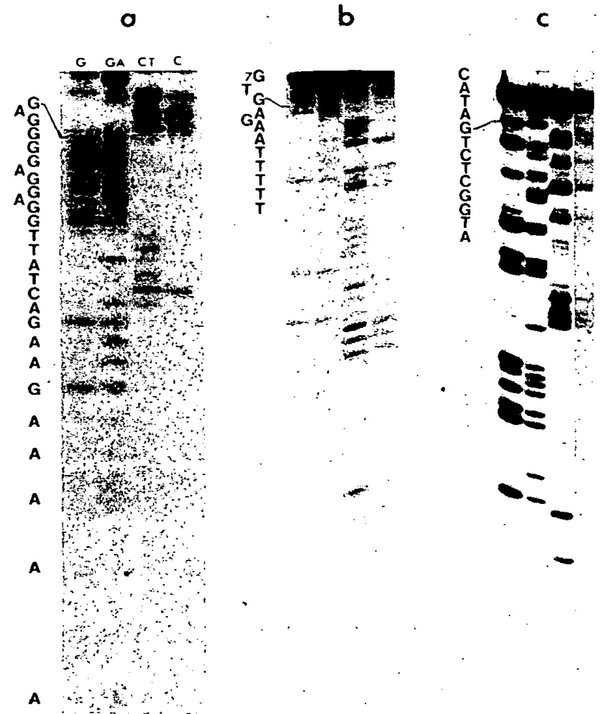

Figure 5. Maxam-Gilbert Sequence Gels Showing the 3′ Termini of the Gaps

(a) Single-stranded Eco RI fragment 3′ ^{32}P-labeled at gap 2; position of first signal corresponds to a dinucleotide (20% gel); (b) single-stranded 5′ ^{32}P-labeled Hinf I fragment with 3′ terminus at gap 3 (8% gel); (c) single-stranded 5′ ^{32}P-labeled Bgl II fragment with 3′ terminus at gap 1 (8% gel).

these fragments revealed that the more slowly migrating of the two species contained gap 2, giving rise to three 5′ labeled single-stranded fragments upon strand separation, two of which originated from the restriction cuts and the third from the gap, whereas the other fragment, although otherwise identical in sequence, consisted only of the two uninterrupted complementary strands.

3′ Extremities of the Gaps

Volovitch et al. (1979) have reported that homopolymer tracts may be added at all three gaps in native CaMV DNA with terminal deoxynucleotidyl transferase, indicating that the 3′ terminal nucleotide of each discontinuity has a free 3′ OH group, but only in the case of gap 2 have we succeeded in introducing enough label at the 3′ terminal position for sequencing purposes. Nevertheless, a fairly precise localization of the 3′ limits of gaps 1 and 3 was obtained by sequencing short 5′ labeled restriction fragments having the gaps at their 3′ termini. (An appropriat fragment t rminating in gap 2 exists but could not be isolat d in quantities sufficient for sequence analysis.) Starting from a Bgl II site about one hundred residues upstream from gap 1 on the 5′ side (with respect to the discontinuous strand), we were able to read the sequence toward gap 1 for all but the last one or two residues at the 3′ end of this fragment, where the heavily labeled band of undegraded material obscured the specific signals in the sequence ladder (Figure 5c). The sequence so determined extends to within two residues of the 5′ terminal nucleotide of the gap (Figure 6). Thus the single-stranded region separating the 5′ and 3′ ends of the gap 1 discontinuity is no more than one or two nucleotides in length.

Figure 5b shows a sequence ladder for a 5′ labeled Hinf I fragment terminating at gap 3. The fragment has the sequence TTTTTAAGAGTGGGGGGG. . . at its 3′ extremity (the seven dG signals in the final run are not readily visible in the reproduction but can be seen on the original film). Comparing this to the sequence of the complementary strand reveals that, surprisingly enough, the 3′ terminal sequence at the discontinuity *overlaps* the first two residues of the 5′ terminal continuation of the strand (Figure 6).

An even more sizable sequence overlap exists at gap 2. As mentioned above, we were successful in

Figure 6. Sequence in the Vicinity of the Gaps

The sequence corresponding to the β strand is written on the upper line and the complementary α strand on the lower line. Asterisk denotes unusual or modified nucleotide (see text). Dashed arrows indicate the extent to which sequence could be read starting from 5′ labeled restriction cuts upstream of the gap.

fixing a ^{32}P–AMP residue to the 3′ terminus of this gap by incubating Eco RI fragment C with α–^{32}P–ATP and terminal transferase. The fragment with the gap at its 3′ terminus was purified by strand separation and sequenced (Figure 5a). When read in a 5′ to 3′ sense, the last 19 residues of the 3′ terminal sequence of this fragment were found to be identical to the first 19 residues of the 5′ continuation of the strand (compare Figure 5a to Figure 4c). As there is no corresponding sequence duplication in the complementary strand, it follows that one or the other of the redundant sequences must branch off of the double helix as a single-stranded tail, as shown in Figure 6. We suggest that the displaced strand is normally that possessing the free 5′ OH extremity because of the relative ease with which the 5′ extremities of the discontinuities can be labeled with polynucleotide kinase (our unpublished observations).

Figure 6 summarizes the sequence in the vicinity of the three gaps. It can be seen that, while none of the sequences are identical, the 5′ termini of gaps 2 and 3 both fall in regions in which the complementary strand is very rich in C: CCCCCCC (1634–1628) for gap 3 and CCTCCTCCCC (4220–4211) for gap 2. These are the two pyrimidine tracts having the highest C content in the entire molecule. Gap 1 is also close to a C-rich sequence, CCCCCGC (8008–8014), but is separated from it by the symmetric AT tract TTAAAAAATT (8015–8024) mentioned above. The differences in sequence around the gaps presumably reflect differences in function. If so, the proximity of gap 1 to the beginning of the coding region leads naturally to the idea that it may be involved in initiation of RNA transcription, but plausible roles for gaps 2 and 3 come less easily to mind. One interesting possibility is that these gaps are start/stop points for replication of viral DNA, as it is evident that redundant terminal sequences like those associated with gaps 2 and 3 could arise if a round of DNA replication proceeds for a short way beyond the original starting point.

Experimental Procedures

Details of the procedure for propagation of CaMV (isolate Cabb B-S), purification of the virus by the Triton X-100–urea method (Hull, Shepherd and Harvey, 1976) and extraction of the DNA have been given elsewhere (Hohn et al., 1980). Digestion of the DNA with restriction enzymes was performed as recommended by the supplier (Biolabs). After restriction, the fragments were dephosphorylated by incubation for 2 hr at 50°C with 0.1–0.5 units of E. coli alkaline phosphatase (Boehringer) per μg DNA. The reaction was stopped by emulsifying with phenol, phenol was eliminated by extraction with ether and the fragments were precipitated with ethanol. The DNA fragments were 5′ end-labeled by incubation at 37°C for 30 min with 0.5 units polynucleotide kinase (Boehringer) per μg DNA in the presence of a 2–5 fold molar excess (with respect to DNA 5′ termini) of γ–^{32}P–ATP (3000 Ci/mmole; Amersham). The reaction was carried out in 70 mM Tris–HCl (pH 7.5), 10 mM $MgCl_2$, 1 mM spermidine, 0.1 mM EDTA, 5 mM dithiothreitol and 25% glycerol. If fragments in which the 5′ termini were flush or recessed were to be labeled, 25% dimethylsulfoxide was included in the reaction mixture.

The ^{32}P end-labeled DNA fragments were separated from one another by electrophoresis through agarose (Hohn et al., 1980) or polyacrylamide (Peacock and Dingman, 1967) gels. Fragments were recovered from agarose gels by the method of Vogelstein and Gillespie (1979). Elution from polyacrylamide gels was by agitation of the crushed gel band overnight at 37°C in 500 mM NaCl, 50 mM Tris (pH 7.9). Soluble polyacrylamide was eliminated by adsorption of the DNA to a small DEAE-cellulose column and subsequent elution at high salt concentration. Fragments were concentrated by ethanol precipitation with 10 μg carrier tRNA.

The 5′ labeled ends of complementary strands were separated by digestion with a second restriction enzyme or, more frequently, by strand separation. Strand separation was carried out by heating the DNA fragment at 90°C for 2 min in the presence of 20% dimethylsulfoxide. The sample was then quick-chilled and immediately loaded on a 5 or an 8% (depending on fragment size) polyacrylamide gel (Szalay, Grohmann and Sinsheimer, 1977).

Singly end labeled DNA fragments were eluted from crushed polyacrylamide gel bands as described above except that the DEAE-cellulose column step was omitted. After addition of 10 μg carrier tRNA, the fragments were ethanol-precipitated, resuspended in 60 mM sodium acetate and reprecipitated, and the precipitate was washed with 90% ethanol. Finally, the precipitate was dried in vacuo and resuspended in a small volume of distilled water for the sequencing reactions.

For labeling 3′ ends, about 2 μg of purified CaMV DNA restriction fragment were dissolved in 25 μl 0.1 M potassium cacodylate (pH 7.6), 1 mM $CaCl_2$, 0.2 mM dithiothreitol (Roychoudhury, Jay and Wu, 1976), and incubated at 37°C for 10 min with 2 units of calf thymus terminal deoxynucleotidyl transferase (PL Biochemicals) and 50 μCi

of α-^{32}P-ATP (New England Nuclear). An additional 2 units of enzyme were added and incubation was continued for 30 min, at which time the mixture was supplemented with 100 nmole ATP and incubated for 10 min more. The DNA was ethanol-precipitated with 5 μg carrier tRNA and the precipitate, collected by centrifugation, was dissolved in 100 μl 1 M piperidine. After heating to 90°C for 30 min, piperidine was eliminated by three cycles of lyophilization. The lyophilized DNA, taken up in distilled water, was subjected to strand separation as described above.

Base-specific chemical cleavage reactions were carried out according to the methods of Maxam and Gilbert (1977), using the methylation reaction for G, depurination for G + A and hydrazine reactions for C + T and C. The cleavage products were fractionated on 8 or 20% 0.5 mm thick polyacrylamide sequencing gels operated at high voltage (Sanger and Coulson, 1978). Autoradiography was performed at −70°C with phosphotungstate intensifying screens. Approximately 75% of the genome was sequenced on both strands with special attention being devoted to those portions of the coding region where there is a shift in reading frame (see Results and Discussion). A computer program was used to search for restriction enzyme sites and sequence overlaps in the course of construction of the sequence, and another program was written to search the finished sequence for potential coding regions and for sequences resembling splice junctions (Lerner et al., 1980). Details concerning derivation of the sequence and photographs of sequencing gels are available upon request.

Acknowledgments

The authors would like to thank G. Lebeurier and A. Lesot for good advice on restriction enzymes and other matters, and G. Daney de Marcillac for computer programming. This work was supported by the Centre National de la Recherche Scientifique.

The costs of publication of this article were defrayed in part by the payment of page charges. This article must therefore be hereby marked "*advertisement*" in accordance with 18 U.S.C. Section 1734 solely to indicate this fact.

Cis-analysis of a seed protein gene promoter: the conservative RY repeat CATGCATG within the legumin box is essential for tissue-specific expression of a legumin gene

Helmut Bäumlein*, Istvan Nagy†, Raimundo Villarroel[1], Dirk Inzé[1] and Ulrich Wobus
Institut für Genetik und Kulturpflanzenforschung, Corrensstraße 3, Gatersleben, O-4325, Germany, and [1]Laboratorium voor Genetika, Rijksuniversiteit Gent, Ledeganckstraat 35, Gent, B-9000, Belgium

Summary

A 2.4 kb fragment containing the 5′-flanking region and the 5′-noncoding sequence of the *Vicia faba* legumin gene *LeB4* mediates high level seed-specific expr ssion in transgenic tobacco plants. Deleted derivatives of this legumin upstream sequence were fus d to the *npt-II* reporter gene to determine the tissue-specific activity of the chimeric constructs in stably transformed tobacco plants. The results indicate the presence of positive regulatory, enhancer-lik *cis* elements within 566 bp of the upstream sequence. Most importantly, however, these elements are only fully functional in conjunction with the core motif CATGCATG of the legumin box around position −95, since destruction of the motif by a 6 bp deletion in an otherwise intact 2.4 kb upstream sequence drastically reduces expression in seeds. At the same tim , low level expression in leaves is observed. The ccurrence of similar CATGCATG consensus *cis* elements with alternating purine and pyrimidine base pairs in front of several other plant genes suggests a functional role of the motif in a wider range of plant promoters.

Introduction

Spatially and temporarily regulated gene expression programmes are the basis for development and morphology. The strictly seed-specific and development-dependent expression of seed storage protein genes provides a suitable experimental system to study differential gene activation in plants.

It is generally accepted that the seed specificity of storage protein gene expression is primarily regulated at the transcriptional level, although post-transcriptional processes can modulate the final amount of translational products widely (Goldberg *et al.*, 1989). Current ideas imply complex interactions between specific *trans*-acting transcription factors with their *cis*-acting target DNA sequences as the principal mechanism for transcription regulation. Several DNA fragments derived from the 5′-flanking regions of different seed protein genes have been shown to bind defined nuclear protein factors (Allen *et al.*, 1989; Bustos *et al.*, 1989; Chen *et al.*, 1988; Jofuku *et al.*, 1987; Jordano *et al.*, 1989). However, in most cases a causal relationship connecting *trans* factor binding with regulated promoter activity has not been demonstrated. The availability of extensive sequence data from 5′ flanking regions of storage protein genes isolated from several different species has prompted the search for conserved sequence motifs, assuming that these elements might be involved in *trans* factor binding and therefore in the regulation of seed protein gene expression. Thus several sequence conservative, putative regulatory DNA elements have been identified (for review see Okamuro and Goldberg, 1989); among them the legume 12S globulin gene-specific legumin box (Bäumlein *et al.*, 1986) with the internal, highly conserved RY core motif CATGCATG (Dickinson *et al.*, 1988).

Recently we have shown that about 1.2 kb of the legumin B4 (*LeB4*) gene upstream sequence is sufficient for strong seed-specific activity and that deletion derivatives with only 193 bp and 91 bp of upstream sequence are approximately 10 times less active (Bäumlein *et al.*, 1991a). For a more precise localization of the *cis* elements which might be responsible for this reduction in activity we have constructed and analysed a series of new deletions.

In this paper we present data extending our knowledge of functionally important DNA sequences in the 5′-flanking region of the gene *LeB4*. In particular, we demonstrate that strong legumin promoter activity and probably also strict tissue specificity depend on the integrity of the short conserved CATGCATG sequence motif within the legumin box.

Results

Delineation of cis*-acting elements by 5′ deletion analysis*

Earlier experimental data (Bäumlein *et al.*, 1991a) demonstrate the presence of functionally important elements in

the legumin *LeB4* gene upstream sequence between about 1200 bp (*Cla*I site) and 193 bp (*Eco*RV site) in front of the transcription start site. For a more precise characterization of those elements we have analysed the effect of progressive and internal deletions within about 1 kb of the *LeB4* upstream sequence (see Figure 1) on NPT-II reporter enzyme levels in seeds of stably transformed tobacco plants. As a first approximation we interprete the changes in enzyme activity as a reflection of changes in promoter strength.

As shown in Figure 2 the *LeB4* upstream sequence can be deleted to position −701 without an obvious loss of NPT-II activity. The average enzyme activity seems to drop when the sequence between −701 and −566 is removed. However, this transition is not statistically significant, and neither is the increase in activity between construct −844 and −701. A significant (at the 5% level) reduction in expression level can be detected when the promoter is shortened to −471 bp. The 95 bp sequence between −566 and −471 is AT-rich (73%) and includes the motif ATTAATT which partly satisfies the ATT A/T AAT consensus rule (Jofuku *et al.*, 1987). The *Ppu*MI site at position −492 used for the construction of the two internal deletions PC and PR (see Figure 1) is also located within this sequence. This restriction site overlaps a so-called GC element present in all legumin gene upstream sequences surveyed (Rerie, 1989; Rerie *et al.*, 1991).

Another extremely AT-rich (82%) region was removed to obtain construct −407. The enzyme levels produced by this construct are on average less than 10% compared to those produced by constructs −701 or −844. Construct −333 lacks part of a DNA motif with a 20 out of 25 bp homology (see Figure 1) to a promoter sequence of the mainly seed-specifically expressed *USP* gene of *Vicia faba* (Bäumlein *et al.*, 1991b) with no obvious effect. Another significant (at the 1% level) reduction in the expression level is shown by construct −232 in comparison to construct −279. The removed sequence does not show any obvious peculiarity apart from an 11-bp purine stretch.

The question of whether a minimal promoter completely lacking the conservative legumin box is still functional was addressed by the analysis of construct −68. Construct −68 leads to significantly (at the 1% level) reduced but still measurable NPT-II activities in comparison to construct −151. The sequence between position −151 and −68 bp includes the total legumin box and an imperfect direct repeat (TGTCACACACGTtcTGTCACACGT) between position −83 and −60 with similarity both to a motif reported to be present in front of several plant genes (Memelink *et al.*, 1987) and to the CACA motif often found in the upstream regions of seed protein genes (Okamuro and Goldberg, 1989). The effects of even shorter promoter constructs on NPT-II activities in seeds have been compared in a separate experimental series. A 45-bp long

(b)

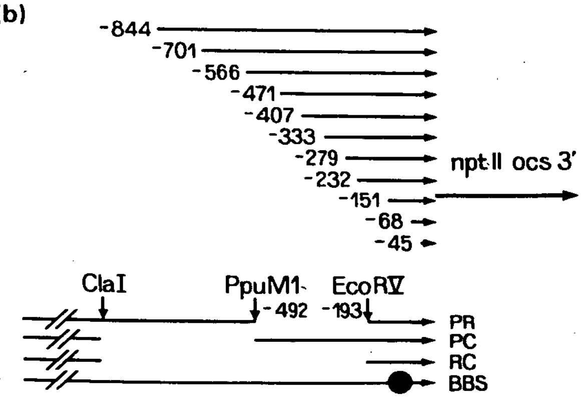

Figure 1. Sequence of the 5′-flanking region of *LeB4* and structure of the *LeB4* promoter deletion constructs.

(a) Sequence of the 5′-flanking region of the legumin gene *LeB4* fused to the *npt-II* coding region in the Ti plasmid pGV180 by a linker region. The start points for deletion derivatives are indicated by * above the sequence and the position number is supplemented by a restriction enzyme symbol in case the respective site was used to create the deletion construct. The *Cla*I site indicated at the top has been mapped to about 50 bp upstream of the given sequence but not sequenced itself. Sequence motifs discussed in the text are marked by underlining and the CATGCATG motif within the legumin box is denoted by italics. The linker region between the last nucleotide of the *LeB4* 5′-noncoding region and the first two codons of the *npt-II* reporter gene are printed in lower case letters. The sequence between positions −689 and +56 has already been published by Bäumlein *et al.* (1986).

(b) Schematic structure of the *LeB4* promoter deletion constructs used in this study. The arrow at the right labelled nptII ocs 3′ symbolizes the neomycinphosphotransferase-II reporter gene terminated by the polyadenylation region of the octopine synthase gene. The other arrows represent *LeB4* sequences upstream of the *npt-II* fusion point indicated in (a) and labelled by the respective deletion end-points. Constructs denoted PR, PC, RC and BBS were created by deletions within the total 2.4 kb *LeB4* upstream region by removing the indicated restriction fragments or, in the case of the BBS construct, by deleting 6 bp of the legumin box core motif CATGCATG, as specified in Figure 3.

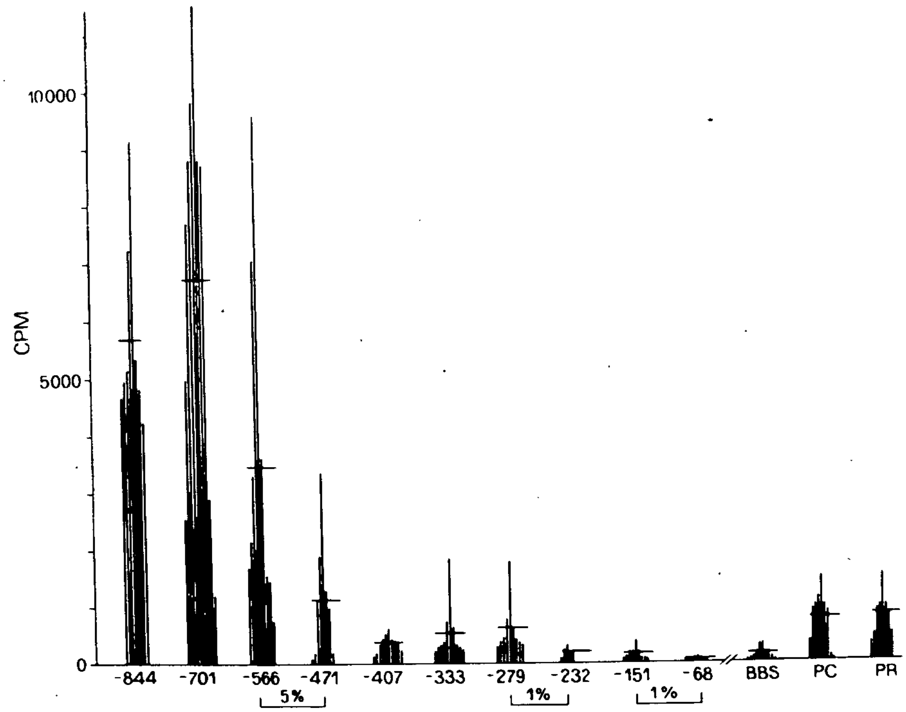

Figure 2. NPT-II activity levels measured by the NPT-II gel assay in mature seeds of independent tobacco plant transformants.
The average value from all plants transformed with the constructs indicated below the columns is denoted by a horizontal line. The constructs are defined in Figure 1. Statistically significant differences at the 1% or 5% significance level between consecutive constructs are indicated by brackets. Fifty micrograms of protein were used in each assay. To keep experimental variability as low as possible, all values given were estimated in a single slot-blot experiment.

promoter (construct −45) still causes low NPT-II activity comparable to that of construct −68. Only the removal of the TATA box in construct −14 completely extinguishes the promoter activity. In addition, a cap site deletion (construct +20) is also inactive, as expected (data not shown).

The progressively shortened promoter constructs described above necessarily change the spatial relationship between the transcription start site and the flanking vector-derived sequences as well as the sequences adjacent to the genomic integration site. To reduce the potential influence of spatial changes we have created and analysed deletions within the 2.4 kb 5′ flanking region (see Figure 1). As shown in Figure 2, both the PR and PC constructs show strongly decreased expression. The low activity of PR confirms the data obtained with the progressive deletion constructs −471, −407, −333, −279 and −232 and demonstrates the necessity of sequence elements between −492 (*Ppu*MI site) and −193 (*Eco*RV site) for optimal promoter function. Moreover, the reduced expression of the PC construct indicates that additional sequence elements at or upstream of the *Ppu*MI site quantitatively affect the expression of the legumin promoter. Considering that sequences upstream of position −566 can be deleted without a significant effect (Figure 2), we conclude that those additional sequence elements are localized closely upstream of or even overlapping the *Ppu*MI site at −492.

The legumin box core motif CATGCATG is essential for seed-specific promoter activity

Assuming that sequence conservation is an indication of functional importance, it has been suggested that the legumin box and its core motif CATGCATG are crucial for legumin gene expression (Bäumlein *et al.*, 1986; Dickinson *et al.*, 1988). To test this hypothesis experimentally we have used a suitable unique *Sph*I site overlapping the CATGCATG core element of the legumin box to specifically remove 6 bp out of the 8 bp core motif (see Figure 3) in the 2.4 kb *LeB4* upstream sequence (BBS deletion). All of the 10 individual transformants analysed show low NPT-II activity in mature seeds, comparable in intensity to the enzyme levels caused by construct −151 (Figure 2). Surprisingly, seven out of the 10 plants transformed with the BBS construct also showed low NPT-II activity in leaves. Examples are given in Figure 4. In contrast, leaf activity is not found in plants carrying constructs with at least 700 bp proximal to the *LeB4* transcription start site (data not shown). To exclude additional unintended changes within the mutated fragment as a cause for the low and tissue-specifically relaxed NPT-II levels, we have confirmed the overall integrity of all BBS constructs by Southern hybridization. Moreover, the removal of the former *Sph*I site was proven by the resistance to *Sph*I treatment of a legumin box containing PCR fragment amplified from genomic DNA of BBS-transformed tobacco

plants. Thus experimental data clearly demonstrate that the destruction of the conservative RY motif CATGCATG within the 2.4 kb upstream region strongly disturbs the function of the legumin B4 promoter.

The AT-rich RC fragment enhances the activity of a truncated foreign promoter

Earlier experimental data (Bäumlein *et al.*, 1991a) demonstrate that the generally AT-rich region between positions

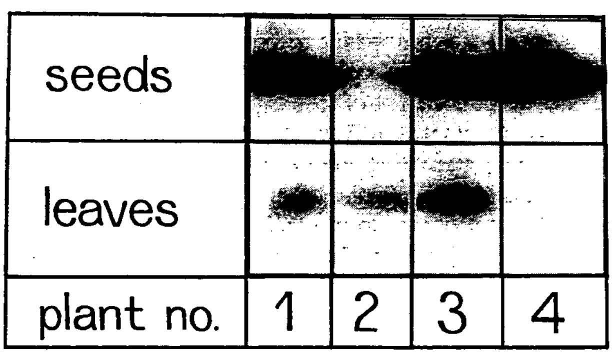

Figure 4. NPT-II activity in seeds and leaves of four individual plants transformed with the BBS construct.
All extracts containing 50 μg of protein were assayed on the same gel and the autoradiogram exposed for 3 days. Note that there is no obvious correlation in activity between seeds and leaves in each construct.

−1200 (*ClaI* site) and −193 (*EcoRV* site) exhibit a clear-cut quantitative effect on the basic *LeB4* promoter. The same promoter region can also co-operate with the truncated *nos* promoter in the Ti-plasmid-derived vector pGV300 which contains 148 bp of upstream sequence still including the b, a, z and reversed b element configuration (Ebert *et al.*, 1987). As shown in Table 1, the RC fragment in constructs RCD+ and RCD− enhances the activity of the truncated *nos* promoter in leaves more than 25-fold, independent of its orientation. Surprisingly, in seed tissue, the enhancing effect is only two- to fourfold; the difference in NPT-II activity between the two orientations is not statistically significant. In contrast to the RC fragment, a legumin box containing *MboII* fragment (positions −155 to −77 in Figure 1) in constructs LBL+ and LBL− does not (or only weakly) interact with the *nos* promoter in seeds, whereas in leaves the reverse but not the natural orientation increases *nos* promoter activity about sixfold (Table 1).

Discussion

Several upstream elements quantitatively influence the legumin promoter activity

The functional analysis in transgenic tobacco plants of a series of deletions covering about 1 kb of *LeB4* gene upstream sequences specifies further earlier conclusions about *LeB4* promoter regulation (Bäumlein *et al.*, 1991a). As shown in Figure 2 there is a highly significant decrease in activity when constructs −701 and −471 are compared. The data suggest that the region distal of −566, but certainly distal of −701, is of little importance for high promoter activity in contrast to the region downstream of bp −566. This region up to bp −407 is rich in AT base pairs. Similar AT-rich sequences have been described as being involved in the regulation of genes coding for seed and other plant proteins. These sequences preferentially interact with high mobility group (HMG) proteins which seemingly recognize certain structural features instead of specific primary sequences (reviewed by Weising and Kahl, 1991). Within these AT-rich sequences lies the *Ppu* MI site-overlapping, evolutionary conserved GC element AAGGTCCCT (Rerie, 1989; Rerie *et al.*, 1991). We take its sequence conservation and the reduced NPT-II activity of the PR and PC constructs (Figure 2), in which either the 5′ or the 3′ part of the *PpuMI* site are removed, as an indication of the functional importance of the GC element.

Another significant transition in activity, although already at a low level, occurs when the fragment between positions −151 and −68, containing the legumin box, is removed (Figure 2). Whereas the BBS deletion clearly reveals the importance of the legumin box core motif CATGCATG (see below) the role, if any, of the additional box sequences

Table 1. Effect of *LeB4* upstream region fragments on a truncated *nos* promoter in transgenic tobacco plants

	Mean (± SEM) value of NPT-II activity (c.p.m.)		Total number of plants
	Seed	Leaf	
pGV300	120 ± 12	343 ± 111	9
LB14	179 ± 17*	344 ± 46	2
LB11	139 ± 11	2038 ± 743**	10
RCD37	270 ± 64**	9790 ± 3975**	4
RCD2	500 ± 195**	9202 ± 3298**	4

pGV300 is the control Ti plasmid described in Experimental procedures containing the truncated *nos* promoter fused to the *npt-II* gene. We fused either the legumin box containing promoter fragment −156 to −77 in the natural (LBL+) or the inverse orientation (LBL−), or the RC fragment (−1200 to −193), again in either the natural (RCD+) or the inverse orientation (RCD−) in front of the truncated promoter. Fifty micrograms of protein extracted from leaves or mature seeds of a total of 29 transgenic plants were analysed by the NPT-II gel assay. Significant difference, at the *5% or **1% level, between a given construct and the control pGV300 in either seeds or leaves as calculated by the Mann–Whitney U test.

around the core motif remains undefined. The low but significant NPT-II activities in seeds of plants transformed with the *LeB4* promoter constructs −232, −151 and −68 are in contrast to results reported by Shirsat *et al.* (1989) and Rerie *et al.* (1991). These authors tested promoter deletions of the pea legumin gene *Leg1* by estimating Leg1 protein levels in transgenic tobacco seeds and were unable to detect any expression when upstream sequences of only 97 bp, 124 bp and 237 bp control legumin expression. The difference between these and our results may be explained by the lower detection sensitivity of the immunological technique used by Shirsat *et al.* (1989) and Rerie *et al.* (1991), although differences due to the constructs used (intact gene versus chimeric gene) cannot be excluded. Presently we cannot fully explain the results of *nos* promoter stimulation by *LeB4* promoter fragments (see Table 1) but we initially conclude that (i) the AT-rich RC fragment contains sequences which meet the criteria for enhancers (Müller *et al.*, 1988) in stimulating the foreign minimal *nos* promoter in an orientation-independent manner, especially in leaves, and (ii) there is no element within the RC fragment acting as a *seed-specific* enhancer in the given construct.

The CATGCATG motif – a key element of the legumin gene promoter

The sequence motif CATGCATG is conserved among legume seed protein genes (Dickinson *et al.*, 1988) and is part of the 28 bp legumin box found in front of genes coding for 12S legume seed globulins (Bäumlein *et al.*, 1986). The exclusive deletion of 6 out of 8 bp of the CATGCATG motif within the 2.4 kb *LeB4* upstream sequence in front of the *npt-II* reporter gene leads to a dramatic reduction of NPT-II enzyme levels (see Figure 2). However, since similar reductions are caused by progressive deletions (−232, −151) leaving the CATGCATG motif intact, we conclude that this motif is necessary but not sufficient for optimal promoter function. These data also explain why we were unable to demonstrate the functional importance of the legumin box using progressive deletions only (Bäumlein *et al.*, 1991a) and imply that the legumin box core element CATGCATG can only function properly in co-operation with additional upstream elements.

Destruction of the CATGCATG motif also causes low NPT-II activity in leaves of BBS plants (Figure 4). Such leaf activity has been already observed in plants carrying the RC deletion construct (see Figure 1) as well as −193 and −91 constructs (Wobus *et al.*, 1989). Relaxed tissue specificity was also reported for shortened patatin-1 promoter constructs (Jefferson *et al.*, 1990) and for a truncated anonymous root-specific promoter (Koncz *et al.*, 1989). We favour the idea that the *LeB4* promoter loses its tissue specificity when the promoter is turned down by the removal or destruction of important *cis* elements. However, we have still not rigorously excluded other explanations, such as an unknown role of the *npt-II* coding sequence, as described for mammalian cells by Artelt *et al.* (1991).

The CATGCATG motif also occurs in other plant gene promoters

Although originally described as an element specific for legume seed protein genes, here we suggest that the CATGCATG motif acts as a functional module in a wider range of plant promoters. Figure 3 shows its physical

presence within the upstream regulatory sequences of several plant genes as well as the SV40 *Sph*I enhancer motif. At least for the maize *C1* gene it was shown that the CATGCATG sequence is crucial for its regulation by the *viviparous* gene product Vp1 (McCarty and Carson, 1991; McCarty, personal communication). We presently favour the idea that either a CATGCATG-binding transcription factor or a structural peculiarity due to the alteration of purine and pyrimidine bases, or both, are involved in the integration of a functional transcription complex in seed tissue.

Experimental procedures

Plasmid constructs

Standard cloning, construction and sequencing techniques have been performed following the guidelines given in Ausubel *et al.* (1987) and Sambrook *et al.* (1989). The starting point for the generation of progressively deleted promoter fragments was the plasmid p4/12BB, described previously (Bäumlein *et al.*, 1991a). p4/12BB contains, beside pUC18 vector sequences, a 2.4 kb upstream region with unique restriction sites for *Cla*I (around −1200), *Ppu*MI (−492), *Eco*RV (−193) and *Sph*I (−91) plus the complete 56 bp 5′-untranslated region of gene *LeB4*. The whole fragment is flanked by an upstream *Eco*RI/*Bgl*II/*Sma*I linker sequence and a downstream *Bam*HI site. After cleavage at the *Cla*I site, p4/12BB was partially digested with *Bal* 31, re-cut with *Sma*I and recircularized. The deletion end-points were determined by the Sanger sequencing technique.

To create the BBS construct, plasmid p4/12BB was cut at the *Sph*I site overlapping the CATGCATG sequence motif, treated with T4 DNA polymerase to resect the 3′ protruding ends, and recircularized. The cloned products were sequenced to analyse the extent of the deletion.

The *Ppu*MI site, dividing the *Eco*RV/*Cla*I fragment (RC) into a distal and a proximal part was used to create the two internal deletions, PC (removing the distal *Cla*I/*Ppu*MI fragment) and PR (removing the proximal *Ppu*MI/*Eco*RV fragment).

The deleted promoter fragments were isolated as *Bgl*II/*Bam*HI fragments and cloned in the right orientation into the *Bgl*II site of the intermediate vector pGV180 containing a promoterless *npt-II* gene (see Bäumlein *et al.*, 1991a). Another strategy was applied to create the three promoter constructs −45, −14 and +20. In this case, the unique *Cla*I site of the plasmid pGV180/legP FL (Bäumlein *et al.*, 1991a), containing the same *LeB4* sequences as plasmid p4/12BB described above, was used as the start point for the partial *Bal* 31 digestion. Again the digestion products were cut with *Sma*I to remove the upstream sequences, gel-purified, recircularized, transformed and the deletion end-points determined by sequence analysis.

To test the influence of several *LeB4* promoter fragments on a truncated foreign promoter, we used the enhancer trap vector pGV300, originally designed by Allan Caplan, Rijksuniversiteit Gent. In this plasmid, which was derived from the pGV180 vector (Bäumlein *et al.*, 1991a; Herman *et al.*, 1986) the *npt*-II reporter gene is driven by a truncated *nos* promoter. Using a suitable *Sst*II site the *nos* promoter was shortened to a length of 148 bp, still including the b, a, z and reversed b sequence elements described to be important for (albeit reduced) promoter activity (Ebert *et al.*, 1987). Both the *Eco*RV/*Cla*I fragment (RC) and the legumin box-containing *Mbo*II fragment (LBL) spanning from position −156 to −77 have been cloned in either orientation in front of this truncated *nos* promoter.

Plant transformation

The intermediate plasmids were transferred into the *Agrobacterium* strain pGV2260 by triparental mating and used for leaf disc transformation of *Nicotiana tabacum* cv. Havana as described previously (Bäumlein *et al.*, 1991a). The integrity of all constructs was checked both in *Agrobacterium* and in the plants using Southern hybridization and PCR techniques.

NPT-II assays

NPT-II activity was detected in 100 mg of tissue. Equal amounts of protein determined by the Bradford assay, were assayed for NPT-II activity either by the gel test (Reiss *et al.*, 1984) or the dot technique (Platt and Yang, 1987). For quantification, the radioactivity of cut filter spots was counted. Seed NPT-II activity was determined from each individual transformant and the grouped values compared by the Mann–Whitney U test. In another experiment, equal amounts of seeds (100 mg each) of all transformants harbouring the same construct were mixed, extracted and analysed on a single gel. The principal results (not shown) did not deviate from those shown in Figure 2 for individual transformants.

Acknowledgements

We thank Andreas Czihal, Elke Liemann, Angela Stegmann, Hannelore Weiβ and Thea Tölle for excellent technical assistance, Drs Allan Caplan and Diana Jofuku for helpful discussions, Dr Ute Heim for assistance with DNA sequencing, and Dr Kirk Schnorr for critical reading of the manuscript. UW acknowledges the support given by the 'Fond der Chemischen Industrie'. HB would also like to thank Professor Marc Van Montagu for his hospitality and advice.

Received September 9, 1990

Summary. We have isolated a novel gene, denoted *USP*, from *Vicia faba* var. minor, which corresponds to the most abundant mRNA present in cotyledons during early seed development; however, the corresponding protein does not accumulate in cotyledons. The characterized *USP* gene with its two introns is 1 of about 15 members of a gene family. A fragment comprising 637 bp of 5′ flanking sequence and the total 5′ untranslated region was shown to be sufficient to drive the mainly seed-specific expression of two reporter genes, coding for neomycin phosphotransferase II and β-glucuronidase, in transgenic *Arabidopsis thaliana* and *Nicotiana tabacum* plants. We showed that the *USP* promoter becomes active in transgenic tobacco seeds in both the embryo and the endosperm, whereas its activity in *Arabidopsis* is detectable only in the embryo. Moreover, we demonstrated a transient activity pattern of the *USP* promoter in root tips of both transgenic host species.

Key words: *Arabidopsis thaliana* – β-Glucuronidase – Root tip – Seed protein gene – *Vicia faba*

Introduction

Despite their apparent morphological simplicity, plants express organ-specific and developmentally regulated genetic programs comparable in complexity to those in animal systems (Goldberg 1988; Goldberg et al. 1989). In an attempt to understand this complexity, the gene families coding for seed proteins have been used as a model experimental system in plant molecular biology (Goldberg et al. 1989). These studies are elucidating the basic principles of the regulation of gene expression during embryogenesis and may provide information that can be applied to improvement of seed protein quality.

As in most dicotyledonous plants, the seed storage protein fraction of the fava bean *Vicia faba* var. minor is dominated by its globulin components (Müntz et al. 1986). Structural and functional data are available for the gene families coding for the major 11S legumin and the 7S vicilin proteins (Wobus et al. 1986; Bäumlein et al. 1986, 1987; Weschke et al. 1987; Heim et al. 1989).

We have recently described cDNA clones specific for an Unknown Seed Protein (*USP*) (Bassüner et al. 1988). The corresponding genes are transcribed into the most abundant mRNA present during early seed development with a time profile similar to that of vicilin mRNA. In spite of the abundance of the mRNA, a similarly abundant protein of the expected size (30 kDa) has not been found (Bassüner et al. 1988). This observation indicates that expression levels are controlled both by transcriptional and extensive post-transcriptional processes. As a first step in revealing the underlying regulatory mechanisms we sequenced a *USP* gene and its flanking regions. In addition, we fused the *USP* promoter region to bacterial reporter genes, and describe the complex seed and root tip-specific expression in transgenic tobacco and *Arabidopsis* plants revealed by the histochemical colour reaction for β-glucuronidase (GUS) activity.

Materials and methods

Gene isolation and sequencing. The recombinant phage Vf30.1 was originally isolated from a phage library of the field bean (*V. faba* var. minor) genome (Bäumlein et al. 1986), using a *USP*-specific cDNA as probe (Wobus et al. 1986). A 3.5 kb *Pst*I fragment containing a member of the USP gene family was subcloned in the phage vector M13mp18 for sequencing and in pUC18 for use in further constructions.

The M13 phage insert was sequenced in both orientations using systematic deletions (Hong 1982) and the chain termination method (Sanger et al. 1977). For the processing of the sequence data a modified Pustell computer program was used (Pustell and Kafatos 1986). The transcription start site was determined by primer extension (Ausubel et al. 1987) using the synthetic primer

5′CAAACTCCATTTGACTGGCT3′. A known sequence ladder was used as size marker (Fig. 2).

Plasmid constructs and generation of transgenic plants. For the construction of chimaeric genes consisting of the 5′ sequences (−637 to +51) of the *USP* gene fused to reporter genes encoding neomycin phosphotransferase II (NPTII) or GUS, a unique *Bst*XI site at the ATG start codon was converted into a *Bgl*II site by the insertion of a *Bgl*II linker into the blunt-ended *Bst*XI site and the coding region together with the 3′-flanking sequence was removed. From the resulting plasmid, the flanking and the 5′-nontranslated regions can be obtained as a 680 bp *Bam*HI-*Bgl*II fragment. This fragment was cloned in the appropriate orientation upstream of the promoterless *nptII* gene in the intermediate vector pGV180. This vector is a derivative of pGV150 conferring hygromycin resistance (Herman et al. 1986). For the *uid*A construct the *Bam*HI-*Bgl*II fragment was blunt-ended and cloned into the blunt-ended *Sal*I site of pGUS1 (Peleman et al. 1989). The resulting *Hin*dIII-*Bam*HI fragment containing the chimaeric *USP-uid*A fusion was used to replace the *Hin*dIII-*Bgl*II fragment of the binary vector pGA472 (An et al. 1985). The plasmids were transferred into the *Agrobacterium* strain pGV2260 (Deblaere et al. 1985) by triparental mating and used for the transformation of *Nicotiana tabacum* cv. Havana by the leaf disc method (Horsch et al. 1985) and *Arabidopsis* ecotype Columbia by the root transformation method (Valvekens et al. 1988). The integrity of all constructs was checked both in *Agrobacterium* and in plants by Southern hybridization (data not shown).

Genomic blots. To determine the size of the gene family, 10 µg genomic *V. faba* DNA was digested with an excess of *Eco*RI, *Bam*HI, *Hin*dIII, *Bgl*II, or *Sph*I. Lambda DNA added to an aliquot of the reaction mixture was used to check that digestion was complete. After blotting on CCA paper (Hunger et al. 1986) the filter was hybridized (2×SSC, 65° C) with the 3.5 kb *Pst*I fragment labelled to a specific activity of 10^8 cpm/µg by random priming (Feinberg and Vogelstein 1983) and exposed to X-ray film for 2 days.

NPTII and GUS assays. NPTII activity was determined from 100 mg tissue. Equal amounts of protein (determined according to Bradford 1976) from each extract, were assayed by gel electrophoresis (Reiss et al. 1984). For the analysis of the tissue specificity of the promoter, tobacco seeds were hand dissected into embryo and endosperm.

GUS assays were performed basically as described by Jefferson (1987).

For the histochemical analysis, mature seeds were imbibed for 4 h and embedded in a 5% agarose solution in water without fixation. The block of agarose containing the seed was cut in the desired orientation with a scalpel and fixed with Pattex Super Gel (S.A. Henkel N.V., Belgium) on the mounting table of a Vibroslicer (Laborimpex, Belgium). After slicing, the embryo and endosperm in the sections were separated. The sections (approximately 30 µm) were each placed in a drop of 50 mM phosphate buffer, pH 7.0 containing 1 mM 5-bromo-4-chloro-3-indolyl-β-D-glucuronide (X-gluc), 0.1 mM potassium ferricyanide, and 0.1 mM potassium ferrocyanide in a petri dish. Sections were incubated at 37° C for 10 min to 24 h in a humidified chamber and then mounted on microscope slides for photography. Photographs were taken with a Wild MPS51 microscope (Heerbrugg, Switzerland).

Gene expression studies in intact plants were done using sterile seedlings (grown in a 16 h light/8 h dark cycle on K1 medium; Valvekens et al. 1988) that had been placed directly in X-gluc solution or had been cut at leaf, cotyledon, hypocotyl, and root prior to incubation to avoid penetration problems. Embryos were dissected by hand from mature seeds 4 h after imbibition and incubated in X-gluc at 37° C.

Results

Structure of the USP *gene*

Screening of a *V. faba* var. minor genomic library with a *USP* cDNA clone revealed two positive phages one of which (λUSP30.1) was chosen for restriction mapping and sequence analysis. The nucleotide sequence of the 3.5 kb *Pst*I fragment is shown in Fig. 1. By comparison with cDNA sequences (Bassüner et al. 1988), two introns, 81 and 110 bp in length, were localized. The border sequences of both introns obey the consensus rules derived for plant genes (Brown 1986). A comparison with cDNA clones pUSP87 and pVfc13 (Bassüner et al. 1988) locates the polyadenylation site 251 bp downstream from the TAA stop codon (Fig. 1). This 3′-untranslated region contains multiple and overlapping polyadenylation signals with plant-specific features (Joshi 1987a) 10 to 31 bp upstream from the poly(A) site. The TGTGTTT motif often found in 3′-flanking regions of plant genes (Joshi 1987a) immediately precedes the poly(A) site.

The transcription start site of the *USP* gene was determined by primer extension experiments (Figs. 1 and 2). As shown in Fig. 2, two bands of equal intensity mark either an A or a C as the potential cap site. Since 67 out of 79 plant genes listed by Joshi (1987b) employ A at the transcription initiation site, we chose the A as position +1 of the *USP* gene. Conceptual translation of the mRNA defines a polypeptide with no obvious overall homology to any other protein sequence present in protein databases (release 21 of the PIR and release 12 of SWISS-PROT). We note however that the signal sequence coding region (+52 to +198; see Bassüner et al. 1988) is interrupted by the first intron as in a tomato proteinase inhibitor I gene (Lee et al. 1986) and that in both genes sequences up to the intron are remarkably homologous: 28 out of 39 nucleotides are identical and 8 out of 13 encoded amino acid residues are functionally equivalent (a two-codon "deletion" in the *USP* gene is not counted; data not shown).

A search of the 5′ upstream region revealed, besides a TATA box at approximately 30 bp upstream from

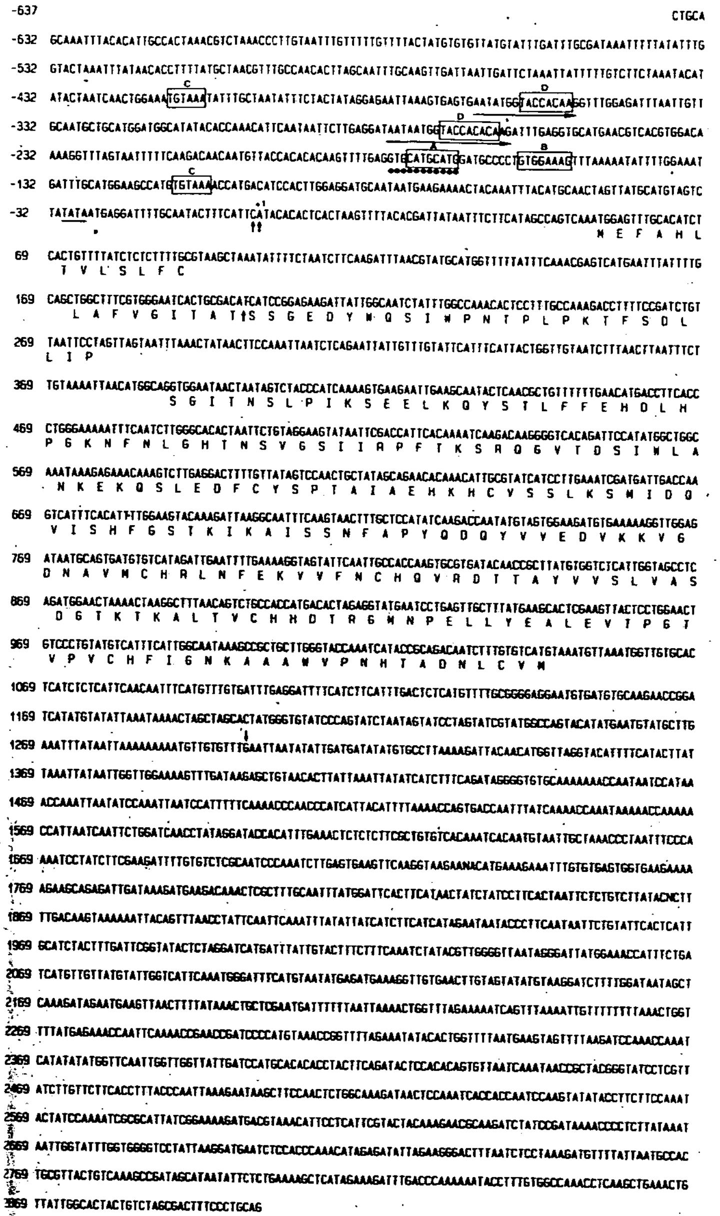

Fig. 1. Sequence of the *USP* gene. The coding region is interrupted by two introns. The *vertical arrow* in the protein sequence marks the position of the presumed signal peptide cleavage point; the *vertical arrow* in the 3′ end of the gene indicates the polyadenylation site, and the *two vertical arrows* in the 5′ region mark the transcription start sites. The CATGCATG box, (A) is part of an 11 bp purine-pyrimidine repeat represented by *dots*. Box B, SV40 core enhancer motif; box C, prolamin box; box D, a sequence present in front of several soybean seed protein genes, which is part of an imperfect direct repeat. The putative TATA box is *underlined* and is located approximately 30 bp upstream from the transcription start

the transcription initiation site, a number of conserved sequence elements (Fig. 1): the seed protein gene-specific CATGCATG motif, which is part of a purine-pyrimidine repeat (Dickinson et al. 1988) at positions −170 to −177, the SV40 core enhancer motif (−154 to −160)

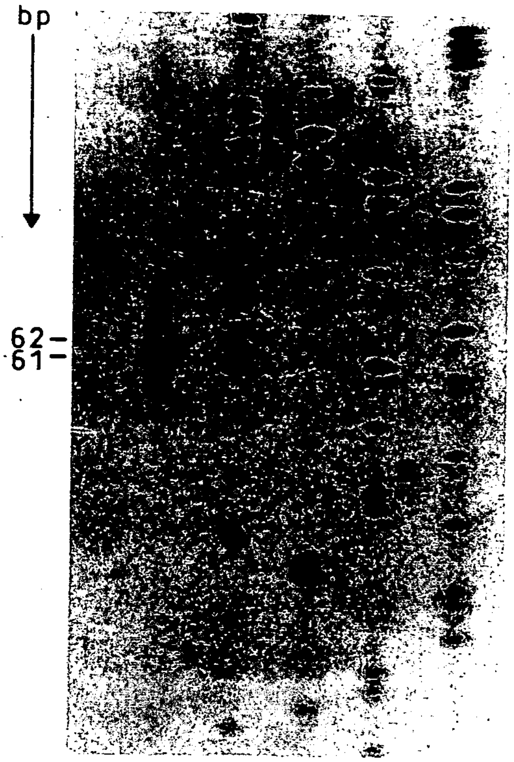

Fig. 2. Determination of the transcription start site by primer extension. Using a known sequencing ladder as marker, the size of the primer extension products were 61 and 62 nucleotides long (see Materials and methods)

GTGGAAAG (Benoist and Chambon 1981), and two copies of the so-called prolamin box (Colot et al. 1987; Matzke et al. 1990) at positions −108 to −113 and −409 to −414. The sequence motifs TACCACAA and TACCACACA found as parts of an imperfect direct repeat in the *USP* promoter (positions −262 to −272 and −352 to −360) closely resemble another sequence element found upstream of several soybean seed protein genes (Goldberg 1986). The importance of all these structurally conserved short sequences for the tissue-specific and development-dependent activity of the *USP* promoter remains to be determined.

The USP *gene family*

Sequence analysis of *USP* cDNA clones had already proven the existence of several *USP* genes (Bassüner et al. 1988). Therefore, genomic hybridization experiments were carried out to estimate roughly the total number of *USP* genes in the *V. faba* var. minor genome, as shown in Fig. 3. By using different restriction enzymes that do not cut within the sequenced *USP* gene we detected approximately 15 hybridizing bands, suggesting that the *USP* gene family consists of roughly 10 to 20 members. This is about the number determined for the legumin *B* gene subfamily (Heim et al. 1989).

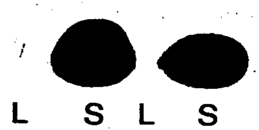

Fig. 4. Comparison of NPTII activity in equal amounts of protein from extracts of seeds (S) and leaves (L) in two independent tobacco transformants

The USP *5′-flanking region confers seed-specific expression on two reporter genes*

We fused a *Bam*HI-*Bgl*II fragment containing 637 bp of the 5′-flanking and the total 5′-untranslated region of 51 bp to a promoterless *nptII* gene in the intermediate vector pGV180 (see Materials and methods) and used it to transform *N. tabacum*. All ten hygromycin-resistant tobacco plants regenerated carried one to five copies of the chimaeric gene (data not shown). With few quantitative differences, all plants produced high levels of NPTII only in seeds as shown in Fig. 4. We never found NPTII activity in leaves, even with a tenfold higher amount of total protein in the assay. Plants transformed with pGV180 alone were NPTII negative in both seeds and leaves. In order to determine the distribution of promoter activity in seed tissues, we hand-dissected developing seeds transformed with the *USP-nptII* fusion construct into embryo and endosperm. Microscopic examination showed contamination of some of the embryos by endosperm but this did not exceed 10%. On the basis of equal protein concentrations we found approximately three- to fourfold higher NPTII activity in embryos as compared with endosperm (mean of three experiments, data not shown). These results were confirmed by analysing hand-prepared embryos and endosperm of seeds transformed with a completely different vector (pGA472) containing the *uid*A gene (coding for β-glucuronidase; Jefferson 1987) fused to the *USP* promoter fragment mentioned above (see Materials and methods). The mean GUS activity in two experiments with samples from five different plants was tenfold higher in embryos than in endosperm. In spite of the quantitative differences between the two experimental series, it is evident that the *USP* promoter is not only active in the embryo but also in the endosperm of tobacco.

Histochemical localisation of GUS activity in seeds and seedlings of transgenic Arabidopsis *and tobacco plants*

Arabidopsis thaliana ecotype Columbia and *N. tabacum* cv. Havana were transformed with a *USP-uid*A fusion gene (see above and Materials and methods) and F_1 seeds and seedlings were analysed for GUS activity. Initially, the F_1 progeny of different independent transgenic lines were analysed. Since the resulting overall staining patterns were similar (data not shown), detailed histochemical analysis was focused on the progeny of two different transgenic lines from each of the two host plants.

GUS activity in seeds. There is a substantial difference in the ability of the GUS substrate (X-gluc) to penetrate different tissues. Seeds especially do not take up X-gluc easily. Therefore, it is difficult to obtain reliable results by staining intact tissues. The problem can be partly circumvented by using a Vibroslicer (see Materials and methods). With this device, unfixed mature seeds can be cut into thin sections prior to the histochemical reaction.

When sections of transformed *Arabidopsis* seeds were incubated in X-gluc, all cells of the embryo as well as the cell layer between the testa and the embryo stained blue. This layer is the outermost cell layer of the endosperm, the so-called aleurone layer. The rest of the endo-

sperm tissue is resorbed by the developing embryo as the seed matures (Vaughan et al. 1971; Bouman 1975).

However, when embryo and endosperm were separated after slicing, but before incubation, only embryo cells showed GUS activity (Fig. 5A, B). The initial result using intact tissue slices can be explained by diffusion of the primary reaction product from cells where it is produced to cells where it precipitates (see Jefferson 1987). However, when an oxidative catalyst is used (see Materials and methods), precipitation of the product appears much faster and more localized. In the presence of the oxidative catalyst, sections with embryo and endosperm do not stain in the endosperm. The reaction is seen first in the palisade parenchyma cells of the cotyledons. Subsequently, blue precipitate is localized in the provascular bundle and protoderm of the axis. After prolonged incubation, weaker blue stain is present in all other cells of the embryo (Fig. 5C).

In contrast to *Arabidopsis* seeds, when tobacco seed slices were stained after separation of endosperm and embryo, GUS activity could be detected in both tissues, thus demonstrating a difference in tissue-specific expression of the chimaeric *USP-uid*A gene in the two heterologous hosts *Arabidopsis* and tobacco (Fig. 5D, E).

GUS activity in seedlings. To analyse the distribution of GUS activity during early plant development, seedlings were taken at different times after germination and stained in X-gluc solution.

Germinating seedlings of *Arabidopsis* turn completely blue upon overnight incubation with X-gluc. Shorter incubation periods reveal differences. Whereas the cotyledons show patches of blue stain, the radicle is uniformly dark blue (data not shown). In germinated seedlings (fully expanded cotyledons), the blue precipitate can be detected in the root with decreasing intensity towards the root tip, whereas the root tip itself is deep blue. Root hairs also contain the precipitate. Upon longer incubation, blue precipitate can also be observed in the vascular bundle, mesophyll cells and epidermal cells of the cotyledons and the hypocotyl (Fig. 5F).

At a later developmental stage, when the first true leaves occur, GUS activity is still present in the root, but the staining is much weaker. It is not detected in leaves, even when they are cut to facilitate penetration of the substrate. In 10% of the seedlings, weak blue staining is also detected in the vascular bundle of the root. The root cap cells and the root meristem show the highest GUS activity.

During the early stages of secondary root formation (up to approximately ten roots per individual plant), GUS activity can only be detected in the cotyledons and in a low percentage of the root tips. We observed that at this stage 10%–20% of the plants no longer show root tip activity, 70%–80% of the plants show GUS activity in only a few root tips (ranging from 10% to 90% of the root tips), and in 10%–20% of the plants, all of the root tips turn blue (Fig. 5G, H). At later stages in development, up to bolting, these relative numbers shift towards plants having no root tip activity at all. GUS activity in the root tips does not seem to be correlated with the age of the side roots, since young side roots do not always have this activity. Roots of mature plants were always GUS negative. In all experiments described, the root system was cut just below the hypocotyl prior to incubation to avoid contamination due to GUS activity in other parts of the plant, e.g. the hypocotyl or cotyledons.

In *N. tabacum*, the pattern of GUS activity in seedlings is very similar to that of *Arabidopsis*. The root tip activity is initially very strong (Fig. 5I). When the plant matures (two-leaf stage), activity is detected mainly in the root cap cells but only after prolonged incubation in X-gluc solution (30 h), suggesting a decrease in the activity of the *USP-uid*A construct. As described for *Arabidopsis*, this activity is not always present in all root tips. The individual plants can have root tips that stain blue, as well as root tips that remain uncoloured (Fig. 5J).

Discussion

Embryo versus endosperm activity of the USP *promoter*

To analyse the tissue-specific promoter activity within seeds we transformed both *Arabidopsis* and tobacco plants with two constructs containing either the *nptII* gene or the *uid*A gene driven by the *USP* promoter. The constructs placed in different vector plasmids share only the *USP* promoter fragment, thereby ruling out possible artificial influences of the neighbouring T-DNA sequences on the expression of the chimaeric genes. When isolated embryo and endosperm tissues from tobacco seeds were tested for enzyme activity, both tissues were found to give positive results with both constructs but with appreciably less activity in the endosperm. The GUS analyses were further confirmed at the histochemical level. In contrast to these results, *Arabidopsis* seeds transformed with the *USP-uid*A construct show activity only in the embryo but not in the endosperm cell layer. Within the embryos of both species all cells turn completely blue upon incubation with X-gluc if no catalyst is used. Addition of ferro-ferricyanide as an oxidative catalyst remarkably enhances the cell specificity of the reaction. First, a reaction is seen in the palisade parenchyma cells of the cotyledons and in the provascular bundle and protoderm of the axis. After longer incubation, weak blue staining is localized in all other cells of the embryo. This weak blue staining could reflect weaker expression of the *USP-uid*A gene in these cells, but could also be due to diffusion of the breakdown product of X-gluc. Similar experiments were carried out with seeds of *Arabidopsis* transformed with a chimaeric gene consisting of the regulatory sequences of *at2S-1*, one of the four genes coding for the 2S napins in *Arabidopsis* (Krebbers et al. 1988a), coupled to the coding sequence of the *uid*A gene. In these thin sections the reaction was first detected in the endosperm. Subsequently, blue precipitate was observed in the spongy parenchyma cells of the cotyledons and the ground meristem cells of the axis (W. Boerjan, unpublished results).

These results indicate that the spatial expression pattern observed with the *USP* promoter is very specific and reflects the amount of β-glucuronidase present in the different cell types, and is not due to artefacts such as penetration and differences in cell size.

The difference in the expression pattern of a heterologous gene in two plant species may reflect differences in regulation due to the ability/inability of *trans*-acting factors to recognize the *cis*-acting elements of the foreign *USP* promoter in the respective endosperm. In any case, data obtained from gene expression studies in heterologous host plants should be interpreted with caution and cannot be generalized. The situation is further complicated by the fact that we do not know how the *USP* promoter behaves in the homologous *V. faba* background, because there is only a rudimentary endosperm in legumes, which disappears at early developmental stages. The only available data pertinent to the problem are for soybean. In this species two seed protein mRNAs coding for Kunitz trypsin inhibitor and β-conglycinin cannot be detected in the endosperm before it disappears during embryogenesis (Perez-Grau and Goldberg 1989). This observation suggests that seed storage protein genes of legumes become active exclusively in the embryo and, as several studies have shown (for a review see Goldberg et al. 1989), that this behaviour is maintained in transgenic tobacco plants. However, this is not true for all investigated genes, since legumin genes *LegA* from pea (Croy et al. 1988) and *LeB4* from fava bean (Wobus et al. 1989; Bäumlein et al. 1990) are active in both the tobacco embryo and endosperm. Such differences in tissue-specific expression between different seed protein genes are most obviously demonstrated in the case of two β-conglycinin genes of soybean: one is active only in the tobacco embryo (Barker et al. 1988), another in both the embryo and the endosperm (S.J. Barker and R.B. Goldberg, unpublished results).

Histochemical localisation of GUS activity in seedlings of transgenic Arabidopsis *and tobacco plants*

There is a substantial difference in the ability of the GUS substrate to penetrate different tissues. Roots, for example, take up the substrate very fast in comparison with the cotyledons, which in fact need to be cut or squashed to enable adequate penetration. Therefore it is difficult to use histochemical techniques to obtain an idea about the absolute levels of GUS enzyme, let alone promoter strength, when comparing different tissues. Another parameter that impedes attempts to correlate directly the appearance of the blue precipitate with promoter activity is the high stability of the β-glucuronidase. As the half-life of GUS in germinating seeds is about 48 h (Bustos et al. 1989) it is difficult to determine whether the blue colour detected in seedlings is due to the presence of stable enzyme synthesized during seed development or to newly formed GUS. We tend to attribute the GUS activity in cotyledons and roots (with the exception of the activity in the root tip; see below) of young seedlings to stable enzyme synthesized previously during embryogenesis, but cannot exclude reactivation of the promoter.

Variation in root tip activity

In transformed *Arabidopsis* as well as tobacco plants, root tip activity is strong in the early stages of development (1- to 2-week-old seedlings) and ceases upon maturation. Moreover, plants that already have a well-developed root system with secondary roots do not always show activity in all root tips. Roots showing root tip activity are morphologically indistinguishable from roots lacking this activity.

The fact that side roots can also have root tip activity suggests that this activity is due to de novo synthesis and not to a residual or redistributed activity of β-glucuronidase synthesized during embryogenesis.

There are several possible explanations for the root tip activity of the *USP* promoter. First, this activity may indicate that the *USP* gene has a specific, but unknown function in root tip tissues. Second, the transient state of activity might well be considered as an evolutionary relic without detrimental effect, but also without functional value. Third, the root tip activity of the *USP* promoter might be due to the structure of the chimaeric gene: it is possible that not all of the control elements needed for *USP* gene expression reside in the 680 bp 5'-flanking region. Fourth, the transfer of the chimaeric gene to a heterologous host, which possibly lacks silencing activities, could also be the cause of the unexpected expression. This explanation is less likely, because experiments with *Arabidopsis* plants transformed with a chimaeric *uid*A gene consisting of the 5'-regulatory sequences of the *ats-1* gene (one of the four genes coding for the small subunit of ribulose-1,5-bisphosphate carboxylase in *Arabidopsis*; Krebbers et al. 1988b), also show root tip activity (W. Boerjan, unpublished results). A similar result has been obtained with transgenic *Arabidopsis* plants that express a chimaeric *at2S-1-gus* gene (see above) (W. Boerjan, unpublished results), thus showing that the expression of certain chimaeric genes in root tips might be a common phenomenon and not due merely to the transfer from one species to another. To exclude the possibility that the root tip activity is due to the structure and/or the transfer of the chimaeric gene, in situ hybridization experiments need to be carried out to determine whether the *USP* mRNA is present in the root tips of *V. faba* itself.

A second question is why not all root tips of a well-developed root system show GUS activity. One might speculate that the root tips are in a developmentally or physiologically different state. The variation in root tip activity could reflect a subtle balance in the interaction between regulatory factors, which may be distorted in a fast-dividing tissue, for example as a result of titration of regulatory factors. Alternatively, one might argue that position effects and copy number differences between the seeds of one transformant with multiple copies play a role in the variation. This explanation is unlikely, because F_1 progeny of a transformed *Arabidopsis* plant,

containing one copy of the *ats-1* gene, which was made homozygous for the T-DNA, also show variation in root tip activity (W. Boerjan, unpublished results).

Currently, we are analysing progressive promoter deletions to identify the *cis* elements responsible for the seed- and root tip-specific expression of the *USP* gene.

Acknowledgements. We would like to thank Andreas Czihal, Elke Liemann, Thea Tölle, Hannelore Weiß, Lieve Ongena, Marianne Habets, and Angela Stegmann for excellent technical assistance. H.B. would like to thank Prof. Kafatos, in whose laboratory the *USP* gene was sequenced, and Drs. Allan Caplan, Diane Jofuku, Jack Okamuro, and Gilbert Engler for helpful discussions. M. De Cock, K. Spruyt, S. Van Gijsegem, and V. Vermaercke are thanked for preparing the manuscript and illustrations. This research was supported by grants of the Services of the Prime Minister (I.U.A.P. 12OC0187), the ASLK-Kankerfonds, and the Kombinat Pflanzenzüchtung und Saatgutwirtschaft Quedlinburg. D.I. is a Senior Research Assistant of the National Fund for Scientific Research (Belgium) and W.B. is indebted to the I.W.O.N.L. for a predoctoral fellowship.

Strategies for the *in vitro* Evolution of Protein Function: Enzyme Evolution by Random Recombination of Improved Sequences

Jeffrey C. Moore, Hua-Ming Jin, Olga Kuchner and Frances H. Arnold*

Division of Chemistry and Chemical Engineering, Mail Code 210-41, California Institute of Technology Pasadena, CA 91125, USA

**Corresponding author*

Sets of genes improved by directed evolution can be recombined *in vitro* to produce further improvements in protein function. Recombination is particularly useful when improved sequences are available; costs of generating such sequences, however, must be weighed against the costs of further evolution by sequential random mutagenesis. Four genes encoding para-nitrobenzyl (pNB) esterase variants exhibiting enhanced activity were recombined in two cycles of high-fidelity DNA shuffling and screening. Genes encoding enzymes exhibiting further improvements in activity were analyzed in order to elucidate evolutionary processes at the DNA level and begin to provide an experimental basis for choosing *in vitro* evolution strategies and setting key parameters for recombination. DNA sequencing of improved variants from the two rounds of DNA shuffling confirmed important features of the recombination process: rapid fixation and accumulation of beneficial mutations from multiple parent sequences as well as removal of silent and deleterious mutations. The five to sixfold further enhancement of total activity towards the para-nitrophenyl (pNP) ester of loracarbef was obtained through recombination of mutations from several parent sequences as well as new point mutations. Computer simulations of recombination and screening illustrate the trade-offs between recombining fewer parent sequences (in order to reduce screening requirements) and lowering the potential for further evolution. Search strategies which may substantially reduce screening requirements in certain situations are described.

Keywords: directed evolution; DNA shuffling; random mutagenesis; para-nitrobenzyl esterase

Introduction

Enzymes can be evolved *in vitro* to exhibit new and useful functions. A sampling of the local sequence space of the enzyme is created by mutagenesis; screening or selection directs the evolution towards the desired features. A successful strategy for improving enzyme activity in non-natural environments (Chen & Arnold, 1993) and on non-natural substrates (Moore & Arnold, 1996) has been to accumulate amino acid substitutions over multiple generations of random mutagenesis and screening. In practice, the best variant identified in each generation is chosen to parent the subsequent generation. Other potentially useful variants are set aside, and their mutations must be rediscovered in the evolved protein background in order to become incorporated. Because there is no mechanism other than back mutation for deleting mutations, this approach can also accumulate deleterious mutations, leading to premature termination of an evolving lineage. These are the classical arguments for the benefits of recombination (sex) in evolution (Maynard Smith, 1988). Recombination allows more rapid accumulation of beneficial mutations present in a population. It also makes possible the removal of deleterious mutations which would otherwise accumulate in an asexual population, a phenomenon known to geneticists as Müller's ratchet (Müller, 1932). Recombination can

provide similar benefits for *in vitro* molecular evolution (Stemmer, 1994a,b).

Bacillus subtilis p-nitrobenzyl (pNB) esterase catalyzes the hydrolysis of the para-nitrobenzyl esters of various cephalosporin-type antibiotics, a necessary step in their large-scale synthesis (Zock *et al.*, 1994). Using four generations of sequential random mutagenesis and screening, we evolved a series of pNB esterases up to 30 times more active towards hydrolysis of the pNB ester of loracarbef (LCN-pNB) in aqueous dimethylformamide (Moore & Arnold, 1996). During the fourth generation, a large number (~7500) of pNB esterase clones were screened and partially characterized in order to validate the rapid screening assay. Sixteen improved pNB esterase clones were identified, from which the five most active enzymes (>50% enhancements in activity over the parent enzyme) were characterized. DNA sequencing revealed four unique pNB esterases (Table 1). Due to the limitations of screening, evolved sequences are generated using a low rate of point mutagenesis and typically accumulate a single beneficial mutation per generation. A simple restriction/ligation experiment demonstrated that recombination of mutations present in at least two of those sequences could further improve pNB esterase activity. Recombining gene segments from two improved pNB esterase variants yielded an enzyme twice as active as the best parent. DNA sequencing demonstrated that mutations from each of the two parents were combined in the new sequence (I60V and L334S), while one neutral or slightly deleterious mutation was deleted (K267R; Moore & Arnold, 1996).

Stemmer recently introduced the technique of "DNA shuffling" to create novel genes by recombination of closely-related DNA sequences (Stemmer, 1994b). Because it also introduces new point mutations during reassembly of the DNA fragments, DNA shuffling alone has been effective for directed protein evolution starting from a single sequence (Stemmer, 1994a; Crameri *et al.*, 1996). Questions arise as to how this approach is best implemented and integrated with other *in vitro* evolution approaches such as sequential random mutagenesis. Issues include optimizing the point mutagenesis rate associated with DNA shuffling, determining appropriate screening sample sizes and how many parental genes to recombine, and deciding when to use recombination. Here we investigate the further evolution of pNB esterase by DNA shuffling of the improved sequences generated by random mutagenesis and screening. By following how the genes evolve during cycles of DNA shuffling and screening, we can elucidate the mechanisms contributing to the evolution of function and begin to optimize strategies for *in vitro* evolution. An analysis of the recombination process identifies some of its benefits and limitations for directed evolution and allows a rational choice of mutagenesis and screening strategies.

Results and Discussion

Recombination statistics and screening requirements

To comment on the utility of DNA shuffling in directed evolution, a review of the statistics of recombination of multiple parent sequences is useful. For this discussion, we will assume that the mutations are unique and distributed far enough from one another on the genes that recombination occurs freely between any two. Furthermore, equal amounts of the initial DNA sequences are recombined. Consider the random recombination of three parent sequences, each of which contains a single mutation. Any given mutation will be incorporated into a progeny sequence with a probability of 1/3; the probability of generating the wild-type sequence is 2/3 at each mutation site. This highlights an important consequence of shuffling multiple sequences: there is a statistical preference for the absence of mutation in the progeny. The overall probability of picking a completely wild-type sequence from the recombined library is $(2/3)^3 = 0.30$. The probability of generating a sequence containing a single mutation (a parent sequence) is $1/3 \times (2/3)^2 = 0.15$. Because there are $C_1^3 = 3!/1!2!$, or three such sequences, the overall fraction of parent sequences in the library is 0.45. Thus fully 75% of the sequences in the recombined library are variants already in the evolutionist's possession.

In general, for a recombination system consisting of N sequences and M total mutations, the probability of generating progeny sequences containing μ mutations equals the number of ways a μ-mutation sequence can be generated (C_μ^M) multiplied by the probability of generating any single μ-mutation sequence:

$$P_\mu = C_\mu^M \left(\frac{1}{N}\right)^\mu \left(\frac{N-1}{N}\right)^{M-\mu}$$
$$= \frac{M!}{(M-\mu)!\mu!} \left(\frac{1}{N}\right)^\mu \left(\frac{N-1}{N}\right)^{M-\mu}.$$

Figure 1 summarizes the analysis for recombination of single-mutation parent sequences ($N = M$). The probability that recombination will return the zero-mutation "grandparent" or single-mutation parent sequences remains constant between 73 and 75%; only ~25% of the clones screened have sequences that have not already been examined. The probability of creating individual sequences declines dramatically with increasing numbers of parents. The least frequent sequences are those containing the majority of mutations from the parent population, and the sequence containing all the mutations ($\mu = M$) is of course the rarest. The probability P_M of generating the rarest sequence is $1/N^M$.

Because we are interested in the evolution of function, we need consider only those mutations responsible for functional differences among pro-

DNA substitutions are identified in the context of the three-base codon of the encoded enzyme sequence. Grey background indicates mutations from fourth generation parent sequences. White background indicates new mutations which arose during DNA shuffling. Bold face type indicates translated DNA mutations.

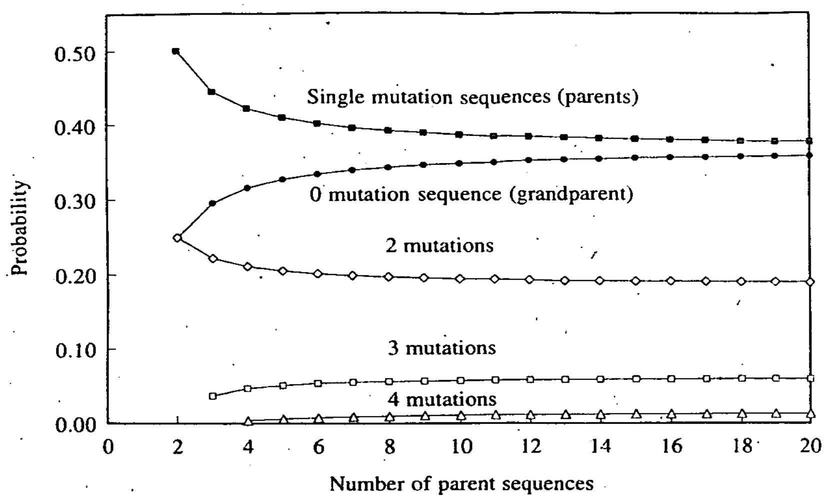

Figure 1. Probabilities of generating sequences containing different numbers of mutations by random recombination, based on recombining single-mutation parent sequences. Novel variants (not grandparent or parent sequences) are shown with unfilled symbols.

tein variants. Neutral mutations by definition do not affect function; their distribution among progeny sequences is determined statistically, even in the screened population (Zhao & Arnold, 1997b). Thus for the purposes of this discussion of recombination libraries and screening requirements, M is the number of mutations that affect the targeted function (either beneficial or deleterious).† By screening enough clones to ensure that the rarest sequence, that is, containing all M mutations, has been examined, one can be sure that the best variant will be discovered. This is true even if the best variant does not contain all the functional mutations (as would be expected if some mutations were deleterious or if the effects of mutations are not cumulative).

In practice, of course, oversampling is required to ensure that a particular variant has been examined during the course of screening. To be 95% confident that the most active combination variant has been examined, we must be 95% confident the rarest variant has been examined. If S is the number of clones sampled, then

$$(1 - P_M)^S < 1 - \text{confidence limit}$$

describes how the probability of not sampling the rarest variant changes with increasing S. This allows calculation of the number of samples required for a given confidence limit. The oversampling is then how many more samples must be screened over the theoretical minimum. When one clone is required with 95% confidence, the oversampling will be between 2.6 and 3.0 (for larger numbers of parents). Even a relatively low rate of background point mutagenesis, however, can introduce significant confounding effects. Non-neutral point mutations obscure recombination events and increase the amount of screening required to find the best sequences (*vide infra*). Thus, in practice, it may be impossible to screen sufficient numbers of clones to be sure of finding the best recombinant, particularly when the point mutation rate is high and a large number of functional mutations are being recombined. Alternative strategies which can reduce screening requirements under special conditions will be discussed further on.

† A mutation that is neutral in one context (i.e. in the wild-type background), but becomes functional in a different context, would be considered a functional mutation.

DNA shuffling of evolved pNB esterases

An effect of forcing DNA polymerase to synthesize full length genes from the pool of small DNA fragments generated during DNA shuffling is additional background point mutagenesis. A high rate of point mutagenesis can severely inhibit the discovery of novel combinations of existing mutations within a population. Because most mutations are deleterious (in a screening assay sensitive to small changes in the screening variable), beneficial recombinations and rare beneficial point mutations are masked by the negative background. DNA shuffling with a 0.7% mutagenesis rate, for example, would yield an average of 10-11 point mutations in the 1470 bp pNB esterase gene. This is substantially more than the optimal mutation frequency (~three mutations per gene) for directed evolution of pNB esterase (Moore & Arnold, 1996). In fact, when the four evolved pNB esterase gene sequences were shuffled using *Taq* polymerase, fully 90% of the clones in the resulting library exhibited essentially no esterase activity during screening (data not shown). In a parallel study, we observed that 80% of the clones generated by DNA shuffling of subtilisin E exhibited no activity (Zhao & Arnold, 1997a).

In an effort to reduce the background mutagenesis rate, a proofreading polymerase (Pwo) was used during fragment reassembly. With Pwo, 50 to 100 base-pair fragments could be reassembled to create a library in which fully 80% of the clones

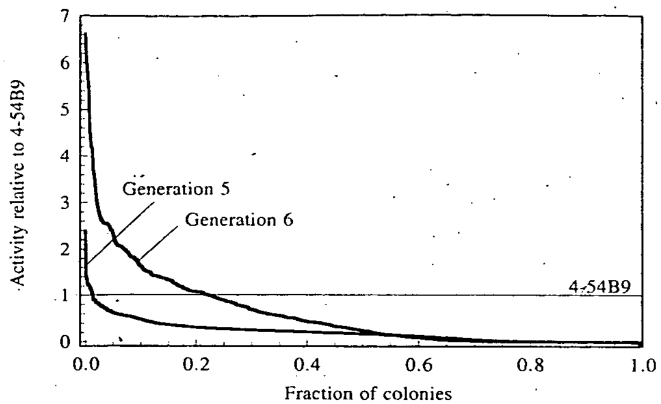

Figure 2. Activity profiles of generations 5 and 6 determined by screening libraries created by DNA shuffling of unique fourth and fifth generation variants. Activities were sorted from best to worst. Profiles are normalized by the number of clones screened.

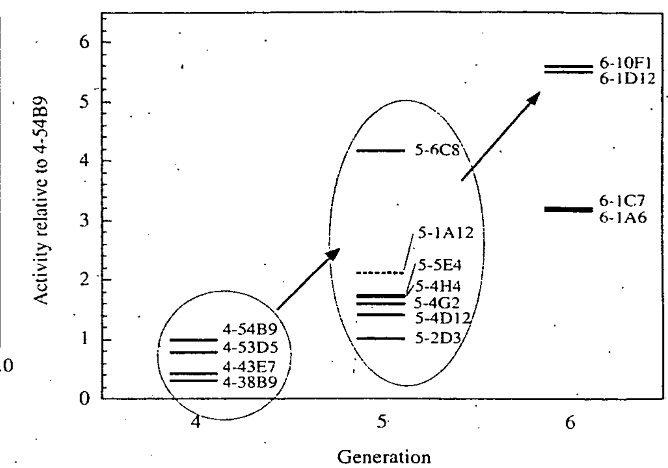

Figure 3. Activities of fourth, fifth and sixth generation pNB esterase variants (Table 1) in screening assay. Fourth generation variants were recombined and screened to identify improved enzymes in generations 5 and 6.

retained activity. Inserts from 13 randomly picked colonies were partially sequenced in order to determine the point mutation rate. Five mutations not present in any of the parent sequences were found in 12,000 nucleotides sequenced, for an overall mutagenic rate of ~0.04%. These minimally mutagenic conditions were used for DNA shuffling. A subsequent, in-depth investigation of the various steps involved in DNA shuffling has allowed us to identify a set of recombination protocols with a wide range of point mutagenesis rates (Zhao & Arnold, 1997a).

Four unique fourth generation improved pNB esterase variants were chosen as the starting point for further directed evolution by DNA shuffling. Two cycles of DNA shuffling and screening for activity towards the *p*-nitrophenyl ester of loracarbef (pNP-LCN) in 25% dimethylformamide (DMF) were performed. The activity profiles of the resulting populations (generations 5 and 6) are shown in Figure 2. To generate these profiles, activities of the individual clones measured in the 96-well plate screening assay were normalized by cell density (A_{600}) and plotted in descending order. Approximately 2% of the 948 generation 5 clones screened exhibit more total activity than the most active parent (4-54B9). The screened population was sufficiently large to give a high level of confidence that the most active variant that can be generated by simple recombination of the fourth generation sequences has been found.† The six most active variants from generation 5 were collected and shuffled again to create generation 6. Fully 20% of the 474 clones screened were more active than 4-54B9. Only 20 to 25% of the clones were inactive, as expected using the high fidelity Pwo-only shuffling conditions.

Figure 3 summarizes the activities of the four fourth generation parents and the best variants identified in generations 5 and 6. The improvement in enzyme activity as a result of shuffling is already apparent in the fifth generation, which includes one variant (5-6C8) fourfold more active than 4-54B9 and twice as active as variant 5-1A12 previously generated by ligation recombination (Moore & Arnold, 1996). The sixth generation contains two clones with yet higher activities than 5-6C8. The best one, 6-10F1, represents a five to sixfold improvement over 4-54B9 and is ~150 times more active than the wild-type.

Activities of the fifth and sixth generation variants towards the *p*-nitrobenzyl ester of loracarbef (LCN-pNB) were also determined, using a modified HPLC assay as described in Materials and Methods. The best pNB esterase is 5-6C8, which exhibits a threefold increase in total activity over 4-54B9. This clone is now ~100 times more active than wild-type pNB esterase towards LCN-pNB in 25% DMF. The sixth generation variants exhibited no further improvement in activity towards this substrate, a clear reflection of the use of the pNP ester during screening and the first law of random mutagenesis: "You get what you screen for" (You & Arnold, 1996).

† When shuffling four parent sequences each of which contains one beneficial mutation, 765 clones must be screened to be 95% confident that all combinations have been examined (assuming recombination occurs freely between mutations and no point mutagenesis). A 0.04% rate of point mutagenesis translates to less than 0.6 new mutations per sequence, of which only a fraction will affect function (estimated from the activity profile of a library created by error-prone PCR to be ~0.5, data not shown).

Analysis of evolved pNB esterase genes

DNA mutations present in the four parent fourth generation sequences and mutations identified by sequencing the genes encoding the selected fifth and sixth generation variants are summarized in Table 1. By comparing the activities and sequences of these variants with the third-generation parent, four beneficial mutations were identified (leading to amino acid substitutions I60V, L334V, L334S and A343V). The remaining mutations present in the fourth generation sequences are neutral or mildly deleterious (Moore & Arnold, 1996).

Several interesting observations can be made from this Table. It can be seen that a number of mutations increase their frequencies in the subsequent generations. Substitutions I60V in 4-38B9 and L334S in 4-54B9 are each present in a single fourth generation parent. In contrast, I60V is present in five of the six fifth-generation variants, and L334S is present in all six. By the sixth generation both substitutions are fixed in the population. A new substitution at position 317, first found during the fifth generation (5-6C8), also becomes fixed by the sixth. This new mutation probably accounts for the significant increase in activity of variant 5-6C8. The P317S substitution is positioned near the enzyme surface in a loop located on the same side of the entrance to the substrate binding pocket as amino acid substitutions L334S, M358V and A343V (Moore & Arnold, 1996). Removal of a proline at this position may relax conformational constraints on the loop, allowing the substrate freer access to the active site.

The two separate beneficial mutations at position 334 in 4-43E7 and 4-54B9 are mutually exclusive, and a competition exists as to which one will be propagated to successive generations. Variant 4-54B9 has more than twice the activity of 4-43E7 as a result of the mutation at position 334, and the fifth generation recombination progeny in fact show the L334S substitution from 4-54B9 exclusively. Recombination provides a rapid means to identify the most effective mutation among multiple possibilities at any given site.

Related to the observation that beneficial mutation combinations are fixed is the fact that recombination and screening also effectively remove neutral and deleterious mutations. Three of the five mutations present in the fourth generation parents that are synonymous (DNA mutations in codons 33, 84, and 239 that do not lead to amino acid substitutions) or non-synonymous, but believed neutral or mildly deleterious in their effects on total activity (mutations leading to amino acid substitutions S94G and K267R (Moore & Arnold, 1996)), have been removed from the improved pNB esterase population in a single round of shuffling; all five are removed by the sixth generation. The two most active sixth generation enzyme variants, 6-10F1 and 6-1D12, have no synonymous mutations at all and only one mutation (at position 359) not seen in any previous clone. Due to the statistical preference for the absence of mutations the recombination process is highly effective in filtering out neutral (and deleterious) mutations starting from multiple parent sequences.

Table 1 also shows that the DNA shuffling technique can recombine multiple parent sequences to create novel progeny. Recombination between at least three fourth-generation parents is required to create 5-5E4, and at least three fifth-generation parents were recombined to generate clones 6-10F1 and 6-1A6 (based on the presence and absence of the DNA mutations in the sequences compared to the parent sequences).

Finally, it is useful to note that DNA shuffling generates point mutations that are rarely observed during PCR (at least for the low-mutagenesis rate PCR conditions used for directed evolution of longer DNA sequences). Four of the 12 new point mutations identified in the fifth and sixth generation variants, for example, are $G \rightarrow C$ (and $C \rightarrow G$) and $G \rightarrow T$ (and $C \rightarrow A$) transversions, which were not found at all during the first four generations of pNB esterase evolution involving PCR mutagenesis (Moore & Arnold, 1996). These mutations were also generated very rarely during the error-prone PCR mutagenesis of subtilisin (Shafikhani *et al.*, 1997). DNA shuffling and error-prone PCR together may provide access to a wider range of amino acid substitutions.

Evolved pNB esterase amino acid sequences

Amino acid substitutions in the evolved pNB esterases are indicated in Table 1; changes in amino acid sequence along the lineage are summarized in Figure 4. The accumulation and fixation of two beneficial amino acid substitutions from the fourth generation, I60V and L334S, is essentially complete in a single generation of DNA shuffling and screening 948 clones. In contrast, A343V, a beneficial mutation found in the fourth generation, no longer appears in the majority of fifth or sixth generation variants. The (5-4H4) recombinant of the parent containing this mutation (4-53D5) with 4-54B9 shows no improvement in activity over 4-54B9 (Figure 3). Substitutions A343V and L334S therefore do not work in concert to improve enzyme activity, and consequently there is little or no driving force to retain A343V in the population. The remaining fifth generation variants, with the exception of 5-6C8, are less active than 5-1A12 (Figure 3), yet they contain the I60V and L334S substitutions while omitting K267R, as does 5-1A12. This suggests that the additional mutations found in those sequences are neutral, or possibly, deleterious. For instance, the amino acid sequences of 5-5E4 and 5-1A12 are identical, and the decreased activity of the former is likely due to the two synonymous mutations in 5-5E4 not present in 5-1A12. Because the screen evaluates the total activity of a clone (normalized by cell density), synonymous mutations can influence the result, for

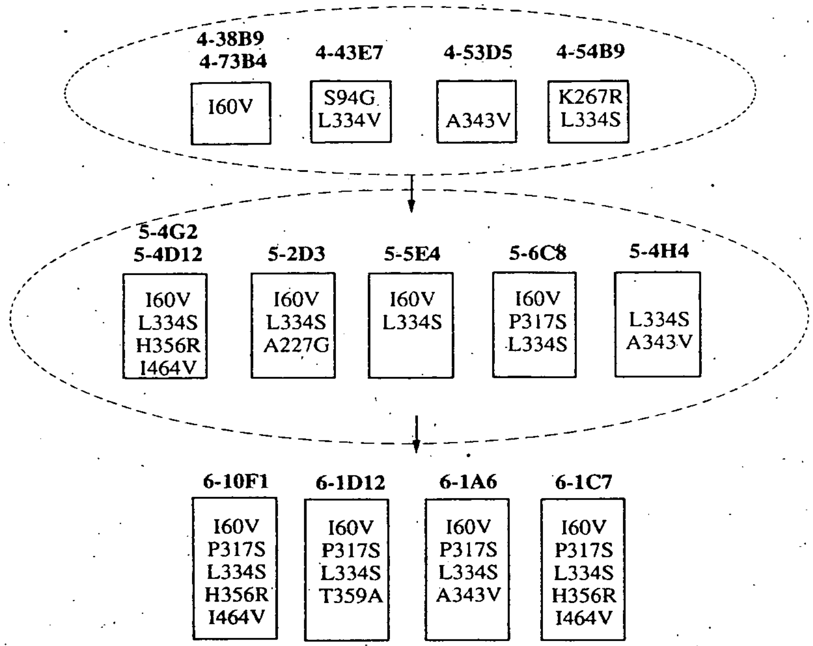

Figure 4. Lineage of pNB esterase variants showing amino acid substitutions accumulated by four generations of sequential random mutagenesis (fourth generation) and by DNA shuffling (fifth and sixth generations) and screening. All variants contain amino acid substitutions H322R, Y370F, M358V and L144M from the third generation parent (Moore & Arnold, 1996).

example, by affecting the amount of active enzyme expressed. The new beneficial mutation that gives rise to the P317S substitution becomes fixed in the sixth generation, and further evolution during that generation primarily arises from point mutation rather than recombination.

Clones 5-4G2 and 5-4D12, whose DNA sequences are identical, both contain amino acid substitutions H356R and I464V. These two substitutions are seen together again in 6-10F1 and 6-1C7. Because 6-10F1 and 6-1D12 have almost identical activity, we can reasonably infer that the I60V, P317S, and L334S substitutions are responsible for that activity, while the mutations leading to H356R and I464V from the fifth generation as well as a new mutation, T359A, in 6-1D12 are neutral. The three mutations believed responsible for enhanced activity are also present in 6-1A6, along with the last mutation in this system known to enhance activity, A343V. That 6-1A6 has lower activity than 6-10F1 and 6-1D12 is therefore attributable to either the three synonymous mutations in 6-1A6 (Table 1) or antagonism between amino acid substitutions A343V and P317S or I60V.

The new point mutations that arose during the minimally mutagenic DNA shuffling increased (P317S) and decreased enzyme activity. The effects of individual mutations can be ascertained with confidence because the sequences differ from one another at very few positions. We have recently demonstrated a method that allows one to distinguish clearly beneficial, neutral and deleterious mutations in evolved sequences by random recombination with ancestor sequences (Zhao & Arnold, 1997b). This method will be particularly useful for identifying mutations responsible for functional changes in proteins in a background of neutral mutations (as happens when multiple new mutations are present).

Only 2% of the fifth generation clones are more active than the most active parent, 4-54B9 (Figure 2). Although 25% of the progeny should be novel, the combination I60V + L334S predominates in the most active variants (Figure 4), suggesting that many of the remaining combinations lead to lower activity than in 4-54B9. Additionally, while there is no mechanism for recombination alone to generate inactive clones, ~25% of the variants in Figure 2 are inactive, presumably as a result of background point mutation. This implies that the frequency of enhanced-activity recombinants is reduced by point mutation and emphasizes the importance of minimizing the mutagenesis rate when recombining positive mutations.

Developing strategies for directed evolution

Recombination versus *random mutagenesis*

Recombination is only useful if a population of sequences is available from which new combinations of mutations can be generated. Homologous proteins with similar sequences could provide such a starting population (Stemmer, 1994b). (Note, however, that a high level of sequence identity may be required for DNA shuffling.) Populations of sequences can also be created by the background point mutagenesis feature of DNA shuffling (Crameri *et al.*, 1996). Alternatively, they can be generated by random mutagenesis and screening experiments, as they have been for the current study. When interesting sequences already exist, recombination offers an efficient means to use that information. If the sequences must be generated, however, then one should consider that

cost in the overall cost of evolution by recombination as compared to, for example, evolution by sequential generations of random mutagenesis and screening.

In theory, the sequential (or "asexual") approach requiring the least labor in terms of screening is to screen randomly mutagenized clones until a positive is identified and then use that as the template for the next generation. The process is a random walk in which the first uphill step encountered is taken. To take a simple illustration, consider three mutations A, B and C that each contribute in a cumulative, if not additive, manner when combined. A, B and C could be collected in the ABC variant in three sequential generations of mutagenesis and screening. Alternatively, if A, B and C all contribute to the desired feature in the wild-type background (as they often do; see, for example, Chen & Arnold, 1993), they could be found separately and then recombined to make ABC. Finding the single-mutation sequences A, B, and C, however, requires screening the same number of colonies as finding ABC by sequential evolution. Recombining the A, B, and C sequences to make ABC requires additional screening. Of course, the sequential pathway requires three random mutagenesis steps, while the recombination pathway requires only one mutagenesis step and one DNA shuffling step. The advantages of one approach over the other then depend on the costs of screening relative to the DNA manipulations.

Note that the severe limitations screening places on the number of colonies that can be sampled makes it difficult to accept downhill steps in the hope that further improvements can be found further out in sequence space (Moore & Arnold, 1997). It also means that extremely rare events such as the recombination of neutral or slightly deleterious mutations to make a beneficial combination will probably not contribute in any significant fashion to the evolutionary process.

The pNB esterase evolution provides a concrete example for analysis. Approximately one in every 1500 to 2000 randomly mutagenized pNB esterase clones screened was positive (showing 50% or greater enhancement in activity over the parent; Moore & Arnold, 1996). To generate the population of four unique positives for DNA shuffling, we examined a total of 7500 clones. Finding the best combination variant required additional DNA shuffling experiments, and ~1400 additional colonies were screened. Thus a total of 9000 clones were screened in going from generations 3 to 6. There is no guarantee that the sequences chosen for recombination are unique: in fact, the original fourth generation clones contained five variants, two of which were identical (4-38B9 and 4-54B9) and two of which contained mutations in the same codon (4-43E7 and 4-54B9), precluding recombination between these variant pairs. It is very likely that variants of comparable or even greater activity could also have been created by continuing random mutagenesis and screening for three generations from the first fourth generation variant identified. The total screening requirement would be the same.

In practice, however, the uphill climb often involves identification of multiple positives during each generation. Everything but the one chosen to parent the next generation is discarded in the random uphill walk of the "asexual" evolution. During the pNB esterase evolution, we often identified four or five potential positives during the rapid screen on the LCN-pNP colorimetric substrate. Those were either verified or not during a second level screen on the *p*-nitrobenzyl (LCN-pNB) substrate, and it was often the case that more than one sequence was a true positive (Moore & Arnold, 1996). The other improved sequences could of course be collected and recombined at any time and at relatively little screening cost. A significant advantage of the DNA shuffling method is its ability to utilize these available positive sequences.

Computer simulations of random recombination and screening

The statistical model can be used to optimize the number of parent sequences chosen for DNA shuffling. Screening during the fourth generation actually resulted in the identification of 16 clones measurably more active than the parent, of which five were at least 50% more active (Moore & Arnold, 1996). An attempt to recombine all 16 sequences yielded no clones more active than 4-54B9 (~1000 clones screened). This result can be understood when we consider the dramatically lower probability of finding the best combination(s) as the number of sequences increases. If the screening sample size is limited to a few thousand clones, there is little chance that the best sequences, or even sequences better than the best parent, will be found by screening a library created from 16 parents.

We have used a computer simulation of the random sampling of the two recombined libraries obtained by shuffling five and ten sequences to illustrate the advantage of choosing fewer parents when screening is limited. Recombining all ten parents becomes advantageous, however, when large numbers of clones can be examined. (Of course, the larger sampling requirement should then be compared to the potential for continued evolution by random mutagenesis.) Assuming that the ten parent sequences each contain a unique, single beneficial mutation ($N = M$) and that they can be recombined to give all possible combinations, we calculated P_μ for $\mu = 0$ through 10. Since $\Sigma P_\mu = 1$, these were organized into a cumulative distribution from 0 to 1, and a random number generator was used to pick a point on the cumulative distribution, thereby identifying μ (number of mutations per sequence). A second random number generator was used to pick one of the C_μ^M possible sequences containing μ substitutions using an evenly spaced distribution of possible

combinations. The activity of the sequence chosen was then calculated by assuming that the free energies of activation of the variants (proportional to the natural logarithms of their activities) are additive.

The results of this simulation are shown in Figure 5, using the activity data from the fourth generation pNB esterase variants. Figure 5(a) shows the averages of the highest values of mutant activities obtained over 15 separate trials for each (screening) sample size. The results obtained by shuffling the ten best mutants (black diamonds) can be seen to be slightly worse than those obtained by shuffling the five best mutants (white squares), for sample sizes up to about 10,000 to 15,000. That is, the average expected best mutant is higher for shuffling five parents at a time for small sample sizes. Figure 5(b) and (c) show the range of values of the highest mutant activity obtained on each of 15 separate trials for each sample size. Here, the highest values obtained from recombining the best ten variants (black diamonds) become better than the values obtained from shuffling the best five (white squares) at sample sizes greater than about 1000. Although shuffling the top ten mutants for this set of data can yield higher final activities, the simulation shows that the outcome is much more risky when screening capabilities are limited to a few thousand clones.

Simulations also show that the results of the comparison of shuffling five *versus* ten parents is highly sensitive to the values of the activities. For instance, if the activities of mutants 6 through 10 are decreased, then the sample size at which recombining all ten mutants becomes preferable becomes much higher. Moreover, the simulation can be adapted for cases in which some or all of the parent sequences have two or more mutations, which may or may not be recombinable. Thus this simulation approach can be used to determine the optimal number of sequences to recombine for any given set of activity values and any given sample size.

The simple additivity assumption on which these simulations are based† is a reasonable first approximation of the behavior of combined mutations in proteins (Wells, 1990) and is useful for a first exploration of strategic issues in *in vitro* protein evolution. The real behavior is often more complex and will depend on the property of interest as well as the particular protein. However, it is likely that deviations from simple additivity are governed by non-linear functions of the number and magnitude of changes; values will certainly depend on which subset of mutations is recombined. While it is possible to modify the simulation to take into account deviations from additivity, very little data are available on the effects of large numbers of mutations. We have therefore not

† Both beneficial and deleterious mutations can be accommodated in this framework.

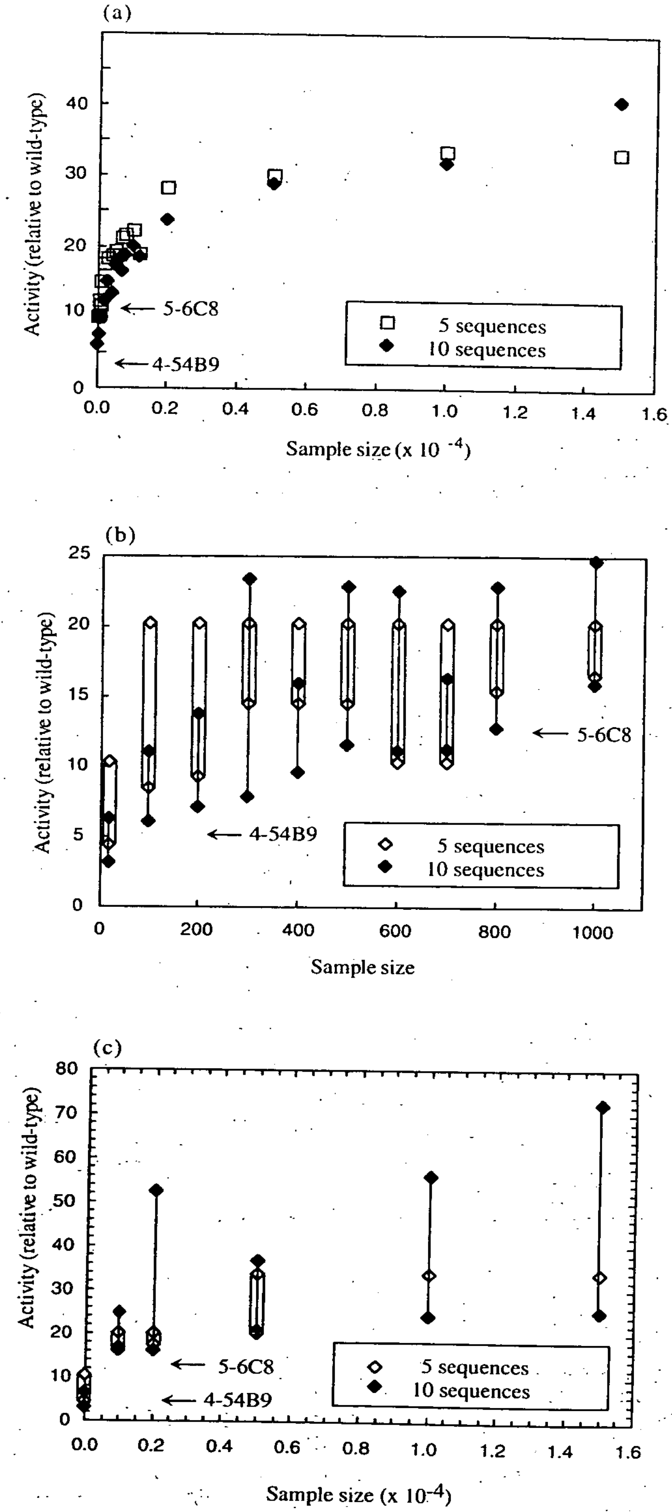

Figure 5. (a) Averages of highest values of mutant activities obtained over 15 separate trials of simulated random recombination of five and ten parent sequences. (b) and (c) Range of values of mutant activities obtained over 15 separate trials. Activities of best fourth-generation parent (4-54B9) and highest-activity fifth generation clone identified (5-6C8) are indicated for comparison.

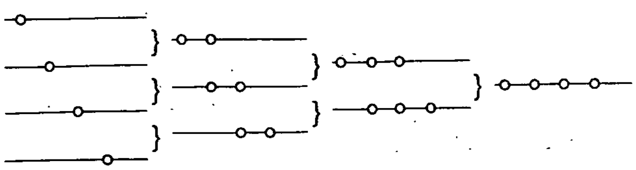

Figure 6. Pairwise recombination can reduce screening requirements, provided effects of mutations are cumulative. By shuffling two sequences at a time, sequences containing two mutations represent 25% of the recombined library. This example involves six recombination experiments.

attempted to include deviations from additivity in the current simulations. Figures 5(a), (b), and (c) show the activities of the best fourth generation parent (4-54B9) and the best fifth generation clone identified (5-6C8) by screening the shuffled library. That the activity of 5-6C8 is ~twofold less than the average expected for screening 948 clones reflects the fact that (i) only four of the original five positive clones identified during generation 4 were unique, (ii) two mutations were on the same codon and could not be recombined, and (iii) the mutations combine with significantly less than 100% additivity.

Alternative search strategies

Finally, we will briefly consider two other search strategies that might be used to minimize screening requirements. One approach to producing a multiple-mutation variant which requires the screening of far less clones is multiple-step pairwise recombination. This strategy is illustrated in Figure 6 for the simple case of recombining four (beneficial) mutations from four separate parents. Pairs of parents are mated. As each progeny is a double mutant 25% of the time, only 12 clones are required to find all the double mutants, assuming the effects of the mutations are cumulative. The double mutants are then similarly mated, and screening only eight clones will identify the triple mutants. Mating and screening four clones will generate the quadruple mutant. Thus a total of only 62 clones (24 × 2.6 times oversampling to be 95% confident at each step) must be screened, as compared to the 765 required to generate the quadruple mutant in a single recombination step. Such an approach requires considerable DNA manipulation and would be most useful when screening is extremely difficult. (An attractive alternative at this point may be sequencing the parents and recombination by site-directed mutagenesis.) A further cost of this approach is that the search space is very limited. The assumption is that each activity-enhancing mutation will contribute to the overall activity, so that the quadruple mutant is the best performer of this population. If a particular double or triple mutant is the best performer, it may or may not be found, since not all of these intermediate mutants will have been examined.

A compromise method that works well, at least in theory, can be described as "population recombination." The idea is to shuffle all four parent sequences at once and screen enough clones to see all the double mutants. Because each double mutant occurs 3.5% of the time, 28 clones must be screened. This examines all of the pair-wise interactions between mutations and eliminates those which are not cumulative. The double mutant population is recombined to produce all of the triple mutants and the quadruple mutant (requires screening 16 clones). If the mutations were at least cumulative in their effects, screening 132 (44 × 3.0 times oversampling) clones would search the space completely for the best (quadruple) mutant. This approach most closely describes how recombination/selection experiments operate (Stemmer, 1994a) where all of the clones that survive a particular selection criterion are recombined (often 100 clones or more serving as the parent population for the next generation).

Conclusions

Recombination is an important tool for directing the evolution of proteins. Beneficial mutations can be recombined, while neutral and deleterious mutations are eliminated. The need to screen rather than select for many important enzyme functions, however, severely limits the ability to search for useful combinations. It is therefore imperative to analyze various recombination strategies. Mutagenic rates associated with the recombination process must be low so that beneficial mutations are not lost in a background of deleterious ones. Although a new beneficial amino acid substitution was found as a result of the DNA shuffling of pNB esterase, DNA shuffling may be less efficient for discovery of new mutations compared to a controlled mutagenesis technique (a beneficial mutation can be masked in the background of recombined sequences). Utilizing more than two parents for recombination introduces a statistical preference for not incorporating mutations in progeny, and this has several consequences especially with respect to screening. Recombination favors the dilution of progeny containing the most mutations, which has the effect of exponentially increasing the number of progeny that must be screened in order to find the rarest ones. Because shuffling large numbers of parent sequences can yield many possible combinations, it may also be necessary to strictly limit the number of parent sequences in any given recombination experiment. We have described two alternative search strategies which reduce the required number of variants examined, at the cost of possibly missing intermediate beneficial combinations.

Finally, recombination requires a population of positive variants for efficient enzyme improve-

ment. If a population of positive variants must first be generated, sequential random mutagenesis may require less effort to produce sequences containing multiple mutations. Multiple positive variants are often generated, however, during a single cycle of random mutagenesis and screening. Recombination of these positives can provide substantial improvements at relatively little cost.

Materials and Methods

DNA shuffling

DNA shuffling was performed as described by Stemmer (1994b) with modifications. The 2 kb DNA fragment encoding the *B. subtilis* pNB esterase gene was amplified using PCR (forward primer 5′-CAATCTAGAGGGTATTAATAATG-3′ and reverse primer 5′-CGCGGGATCCCCGGGTACCGGGC-3′). The amplified DNA was purified by gel electrophoresis and extraction using Qiaex kit (Qiagen, Chatsworth, CA). A total quantity of ~10 μg DNA, either from a single parent (non-recombinatorial) or from a mixture of multiple parent sequences (recombinatorial), was digested with DNase I (0.0015 units/μl) at room temperature for 20 minutes in a 100 μl reaction. After ethanol precipitation, the digested DNA was electrophoresed as a smear in a 3% low melting temperature gel of NuSieve GTG Agarose (FMC Bio Products, Rockland, ME). DNA fragments in specified molecular size ranges were collected onto DE-81 filter paper disks (Whatman, Maidstone, England) by electrophoresis and eluted from the filter paper with 400 μl of 10 mM Tris/1 mM EDTA buffer (pH 8.0) containing 1 M NaCl. The DNA fragments were ethanol precipitated and redissolved to approximately 20 ng DNA/μl in 1 × Pwo DNA polymerase buffer (Boerhinger Mannheim, Indianapolis, IN) containing 2 mM $MgSO_4$ and 0.2 mM each of the four dNTPs. A 5 unit/μl Pwo DNA polymerase solution (Boehringer Mannheim) was diluted tenfold, and 0.5 μl was added to a 5 μl redissolved DNA reaction solution. Reassembly of DNA fragments was conducted by PCR, using the conditions 94°C for 40 seconds., then 70 cycles of 94°C for 30 seconds, 50°C for 30 seconds, 72°C for 30 seconds, followed by a final extension step at 72°C for five minutes. A second 0.5 μl of Pwo polymerase was added at the annealing step of the 35th cycle. The reassembled DNA fragments were amplified in a conventional PCR (25 cycles) with the dilution of 1 μl reassembled DNA fragments in a 100 μl reaction. Once the success of the reassembly/amplification reactions was verified by gel electrophoresis, the reassembled product was purified with a Wizard PCR prep kit (Promega Corp., Madison, WI), digested with *Bam*HI and *Xba*I, concentrated by ethanol precipitation, and electrophoresed in an agarose gel. The 1.8 kb product was cut from the gel and the DNA extracted using a Qiaex kit. The final products were ligated with the vector generated by *Bam*HI-*Xba*I digestion of pNB106R (Zock *et al.*, 1994). This library was used to transform competent *E. coli* TG1 cells, as described (Moore & Arnold, 1996).

Screening a pNB esterase library

Screening was based on the assay described previously (Moore & Arnold, 1996), using the *p*-nitrophenyl ester of the loracarbef nucleus (LCN-pNP) as substrate. *E. coli* TG1 containing the plasmid library were grown on LB/tetracycline (20 μg/ml) plates. After 36 hours at 30°C single colonies were picked into 96-well plates containing 100 μl LB/tetracycline medium per well. These plates were shaken and incubated at 30°C for 12 hours to let the cells grow to saturation. Aliquots (20 μl) of the cultures were inoculated into a fresh plate containing 100 μl media per well; these were incubated at 40°C for ten hours with shaking to induce the expression of pNB esterase. Esterase activities were then measured by transferring 20 μl aliquots of the cell cultures into a fresh set of plates where they were mixed with 200 μl of 0.1 M Tris-HCl (pH 7.0) 25% DMF and 2 mM LCN-pNP. Reaction velocities were measured at 450 nm over ten minutes. (11 data points) in a ThermoMax microplate reader (Molecular Devices, Sunnyvale CA). Activities were normalized by the cell densities of the original wells measured at 600 nm to control for variations in cell quantities.

For each round of screening, the clones that showed the highest activities were re-streaked on LB/tetracycline agar plates, and single colonies derived from these plates (three to four colonies from each clone) were inoculated simultaneously into 96-well plates and tube cultures. The former were used to repeat the activity assay, as described above, and the latter were used for glycerol stock and plasmid preparation (Qiawell kit, Qiagen).

Assay of pNB esterase activity on LCN-pNB

A modified HPLC assay was used to determine enzyme activity towards the LCN-pNB (*p*-nitrobenzyl ester) substrate (Chen *et al.*, 1995). The bacterial cells were incubated at 30°C with shaking for 12 hours and then at 40°C for ten hours to induce expression of pNB esterase. Aliquots of cells (200 μl) were incubated with 300 μl reaction buffer for 30 minutes at room temperature. The final reaction mixtures contained 0.1 M Tris-HCl (pH 7.0) 25% DMF and 2 mM LCN-pNB. The reactions were stopped by addition of 500 μl acetonitrile and passed through a nylon syringe filter (Micron Separations, Inc., Westboro, MA) with a pore size of 0.45 μm. Aliquots of each sample (50 μl) were analyzed by HPLC on a 250 mm × 4.6 mm C18 reverse-phase column (Vydac, Hesperia, CA) at room temperature using a linear gradient starting with 50:50 of A:B (A = 5% methanol/95% 1 mM triethylamine, pH 2.5; B = 100% methanol) and ending with pure B in eight minutes (flow rate of 1 ml per minutes). Product and substrate were detected at 270 nm. The area of the *p*-nitrobenzyl alcohol product peak was calculated and subtracted from the area of the same peak from a sample containing *E. coli* without a pNB esterase gene. This controls for the small quantities of free product in the substrate preparation and any interference from bacterial contamination. This final area was used as a measure of total activity, which was normalized by cell density.

Acknowledgments

The authors thank Dr W. P. C. Stemmer (Maxygen) for many helpful discussions, Dr Steve Queener (Eli Lilly & Co.) for providing us the wild-type pNB esterase and the challenge to evolve it, and Ms Rebecca Little (Eli Lilly & Co.) for assistance with DNA sequencing. This

Applications of DNA shuffling to pharmaceuticals and vaccines

Phillip A Patten*, Russell J Howard† and Willem PC Stemmer‡

DNA shuffling is a practical process for directed molecular evolution which uses recombination to dramatically accelerate the rate at which one can evolve genes. Single and multigene traits that require many mutations for improved phenotypes can be evolved rapidly. DNA shuffling technology has been significantly enhanced in the past year, extending its range of applications to small molecule pharmaceuticals, pharmaceutical proteins, gene therapy vehicles and transgenes, vaccines and evolved viruses for vaccines, and laboratory animal models.

Introduction

The sequence-design processes used by nature have yielded results far superior to those obtained so far by rational approaches to the design of biological structures and systems. The rational design of proteins, for example, is performed by computer modeling of individual changes, followed by construction of the corresponding DNA and expression of the recombinant protein for testing and evaluation. This approach seeks to design proteins for specific tasks by drawing correlations between amino acid sequence and specific shapes in an attempt to understand a complex system through its topography. At its root, our limited ability to rationally engineer complex biological systems stems from three main factors: limited structure/function knowledge of most proteins and of their complex interactions with expression machinery and other molecules within the cell; the computationally intensive and approximate nature of the modelling required; and the fact that the number of relevant mutants for which one would wish to make predictions in order to optimize a given function ranges from millions to numbers of astronomical proportions [1].

In contrast to rational design procedures, nature employs mutation, selection and recombination to evolve highly adapted individuals from the effectively infinite possibilities encoded implicitly in the genome. Recent technological advances have demonstrated that it is now possible to mimic these natural evolutionary processes. Benchtop *in vitro* evolution techniques are used to construct libraries as large as 10^{15} molecules [2–5]. Researchers can mimic natural evolution by searching these libraries by, for example, affinity panning of phage-displayed or RNA ligands against pharmaceutical targets, for the best candidates for a specific task. Repeated rounds of selection and amplification of candidates has already produced improved enzymes and novel molecules capable of binding their targets with higher affinity than their natural counterparts. Unlike natural selection, in which multiple environmental forces select organisms with genomes that allow them to meet a variety of challenges, *in vitro* evolution exerts focused selection pressure on organisms in isolation, enabling the rapid development of variants with highly specialized traits.

Despite the enormous potential of these techniques, determination of the best strategy to exploit this diversity has been the topic of much debate. The most popular methods of creating combinatorial libraries are strategies that seek to evolve sequences that have individual point mutations or blocks of oligonucleotide encoded mutations. At present, most researchers use either repeated cycles of 'error-prone PCR' [6,7] or repeated oligonucleotide directed mutagenesis [8] to create these 'point mutation' libraries. Error-prone PCR employs a low fidelity replication step to introduce random point mutations at each round of amplification [6]. This method has the advantage of simplicity and ease of use. The power of these methods is limited, however, by one's ability to identify critical regions for mutagenesis and because, generally, only small regions of the genome can be mutagenized to saturation and be exhaustively sampled in screens or selections, due to limited library sizes relative to the size of the sequence spaces defined by exhaustive random searches [9].

Iterative cassette or point mutagenesis can overcome some of these limitations; however, as discussed below, DNA shuffling profoundly accelerates the process. In this review we summarize recent advances which extend the range of application of this technique to small molecule pharmaceuticals, pharmaceutical proteins, gene therapy vehicles and transgenes, vaccines, and evolved viruses for laboratory animal models of disease.

Recombination

A key limitation of random point mutagenesis and random cassette mutagenesis strategies can be traced to the fact that they introduce random 'noise' into the gene population at every cycle, and hence improvements are limited to small steps. If the noise level is too high relative to the library size and the selection stringency, the

message will gradually become riddled with deleterious mutations. This is analogous to the phenomenon of Muller's Ratchet [10] from population biology in which, in the absence of sexual recombination, deleterious mutations build up in a population over time. From decades of plant and animal breeding, classical breeders have learned to use recombination to rapidly evolve improved sequences for a specific task. Sexual replication in combination with directed selection can produce substantial improvements in a highly diverse genome within just a few cycles. The widespread prevalence in nature of sexual versus asexual reproduction has been the topic of much debate [11]. A gene favouring parthogenic rather than sexual reproduction would quickly take over in a population unless counterveiled by selection, the so-called twofold cost of sex. One hypothesized major force for the maintenance of sexual reproduction is that recombination of natural diversity allows for populations to rapidly evolve in order to adapt to changing physical environments or pathogens by combining beneficial mutations into single, more fit individuals and deleterious mutations into less fit individuals that are then selected out of the gene pool [11].

The technique of DNA shuffling comes the closest of any laboratory technique to mimicking natural recombination by allowing the *in vitro* homologous recombination of DNA [12,13]. This technique not only recombines DNA fragments, but also introduces point mutations at a very low, controlled rate [14], thus, combining recombination, point mutation, and selection techniques to create a general, parallel algorithm for evolving improved genes. This parallel search strategy is analogous to that used by massively parallel supercomputers [9], such as those used for climate modelling or to factor very large prime numbers. Figures 1 and 2 summarize the practical and theoretical advantages of DNA shuffling relative to existing recursive mutagenesis methods, such as error-prone PCR or recursive oligonucleotide directed mutagenesis. Recent progress with DNA shuffling has clearly demonstrated the utility of recombination for accelerating molecular evolution through simultaneously permuting both single mutations and large sequence blocks (Table 1). DNA shuffling combined with focused selection pressure in the laboratory will allow one to rapidly evolve genes for a wide variety of industrial applications: the optimization of enzymes, such as proteases, lipases, amylases and cellulases; the development of metabolic pathways specialized to synthesize large amounts of specialty chemicals, antibiotics, or pharmaceutical proteins; organisms designed for bioremediation; and plasmids or viruses for novel vaccines and gene therapy applications (Table 2). These emerging applications are discussed below.

Family shuffling dramatically increases the rate of st pwise evoluti n

Forced hybridization between species, such as was performed in the cross-breeding of the plum and apricot to yield the plumcot, was recognized last century by plant breeders as a highly effective method for generating novel, functional varieties with phenotypes differing dramatically from either parent [15]. The utility of this strategy has now been demonstrated at the level of a single gene. To evaluate whether recombining natural diversity accelerates the evolution process, the efficiency of obtaining a new substrate specificity from four homologous enzyme genes evolved separately was compared with that from a recombined pool of the four genes. The essential goal was to compare the rate of evolution of a single gene that is subjected to random mutation and selection to the rate of evolution of a library of genes created by recombining existing, functional genetic diversity present in a family of homologous genes. Since all of the recombinants are created from diversity that has proven functional in the context of its parental gene, the hope is that such libraries would be of much higher quality than random libraries. The results affirm this view. One cycle of single gene shuffling yielded eightfold improvements from each of the four separately evolved genes, versus a 270–540-fold improvement from the four genes shuffled together ([16••]; Figure 3a). This represents an approximately 50-fold increase in the rate of improvement per cycle. The best clone contained eight segments from three of the four genes as well as 33 amino acid point mutations. It is worth emphasizing that this evolved improvement relative to the initial gene pool was obtained in a single cycle of gene shuffling, rather than requiring many recursive cycles.

Thus, in contrast to classical breeding techniques, DNA shuffling allows one to readily recombine DNA derived from 'separate' species or genera. This results in a much more sparse sampling of sequence space (Figure 3b), in which the average similarity between library members is much lower than with other strategies. Sparse sampling yields mutants that, after a single cycle, are far more divergent from the parental genes than is possible with single gene shuffling or point mutation strategies. This recent experiment demonstrates that cross-species recombination is a remarkable accelerant of molecular evolution. Family shuffling will be widely applicable to the commercially important problems discussed below.

Protein pharmaceuticals

Recombinant pharmaceutical proteins form a multi-billion dollar sector of the pharmaceutical industry. This industry relies principally on cloning existing genes encoding cytokines, growth factors, and enzymes that are the products of millions of years of evolution. Many of these products have side effects that cause serious complications which limit or preclude their clinical use. Selective breeding using DNA shuffling provides a technology for rapidly improving pharmaceutical proteins through selective breeding for enhancement of desirable biological activities, while eliminating or reducing undesired activities (Table 2).

Table 1

Genes and operons evolved by DNA shuffling.

System	Improvement	Size	Cycles	Mutations	Comments	Reference
TEM-1 β-lactamase	Enzyme activity 32,000-fold	1 kb	3 + 2†	6 aa	Selection MIC 0.02 μg/ml to 640 μg/ml In comparison, three cycles of mutagenic PCR and selection=16-fold	[12]
β-lactamase family	Enzyme activity 270–540-fold	1 kb	1	Chimerics	Selection 500-fold jump in fitness in one round of shuffling and screening 50,000 colonies	[16]
β-galactosidase	Fucosidase activity 66-fold Substrate specificity 1,000-fold	4 kb	7	6 aa 13 bp	Screen 10,000 colonies per round, best 20–40 chosen per cycle 66-fold fucosidase activity: 2–3-fold increase expression plus 20-fold increase activity 11/13 base mutations in coding sequence	[30••]
Green fluorescence protein	Protein folding 45-fold (*E. coli* and mammalian cells)	0.8 kb	3	3 aa 6 bp	Screen 10,000 colonies per round, best 20–40 chosen per cycle Protein folding improvement	[31]
Antibody (scFv)	Avidity >400-fold	0.8 kb	8 + 2†	34 aa	Phage panning Naive human antibody library Stop codon modified to suppressible stop codon	[32]
Antibody (scFv)	Expression level 100-fold	0.8 kb		5	Phage panning Murine hybridoma library	[32]
Arsenate operon	Arsenate resistance 40-fold	2.3 kb	3	3 aa 13 bp	Selection Three genes; 5.5 kb plasmid shuffled 10,000 colonies per cycle All three mutations in arsB efflux pump, arsC was predicted to be rate limiting Arsenate reduction activity up 5-10-fold Growth in 0.5 M arsenate Plasmid integrated in round 3	[19]
Atrazine degradation	Atrazine degradation 80-fold	5.6 kb	4	8 aa‡	Screen Two genes: 8.5 kb plasmid shuffled Atrazine chlorohydrolase activity increased Wild-type inactive versus terbutylazine, evolved enz active Screen: insoluble atrazine to soluble product gives zone of clearing	
Alkyl transferase	DNA repair 10-fold	0.5 kb	6	7 aa	Selection Suicide enzyme: limited potential for improvement	FC Christians, G Dawes, WPC Stemmer, unpublished data
Benzyl esterase	Antibiotic deprotection 150-fold	1.5 kb	2	8 aa	Screen Four rounds of PCR mutagenesis and screening for improved variants prior to shuffling	[20]
tRNA synthetase	Charging of engineered tRNA 180-fold	2.0 kb	7	nd	Selection	[22]

†Additional backcross cycles. ‡Rare mutation: 3 NA insertions in 5 codons restored frame, inserted 1 aa with 5 other aa changed atz gene lost 2 kb in final mutant, no loss of function. aa, amino acid changes; bp, base pair changes; nd, not determined.

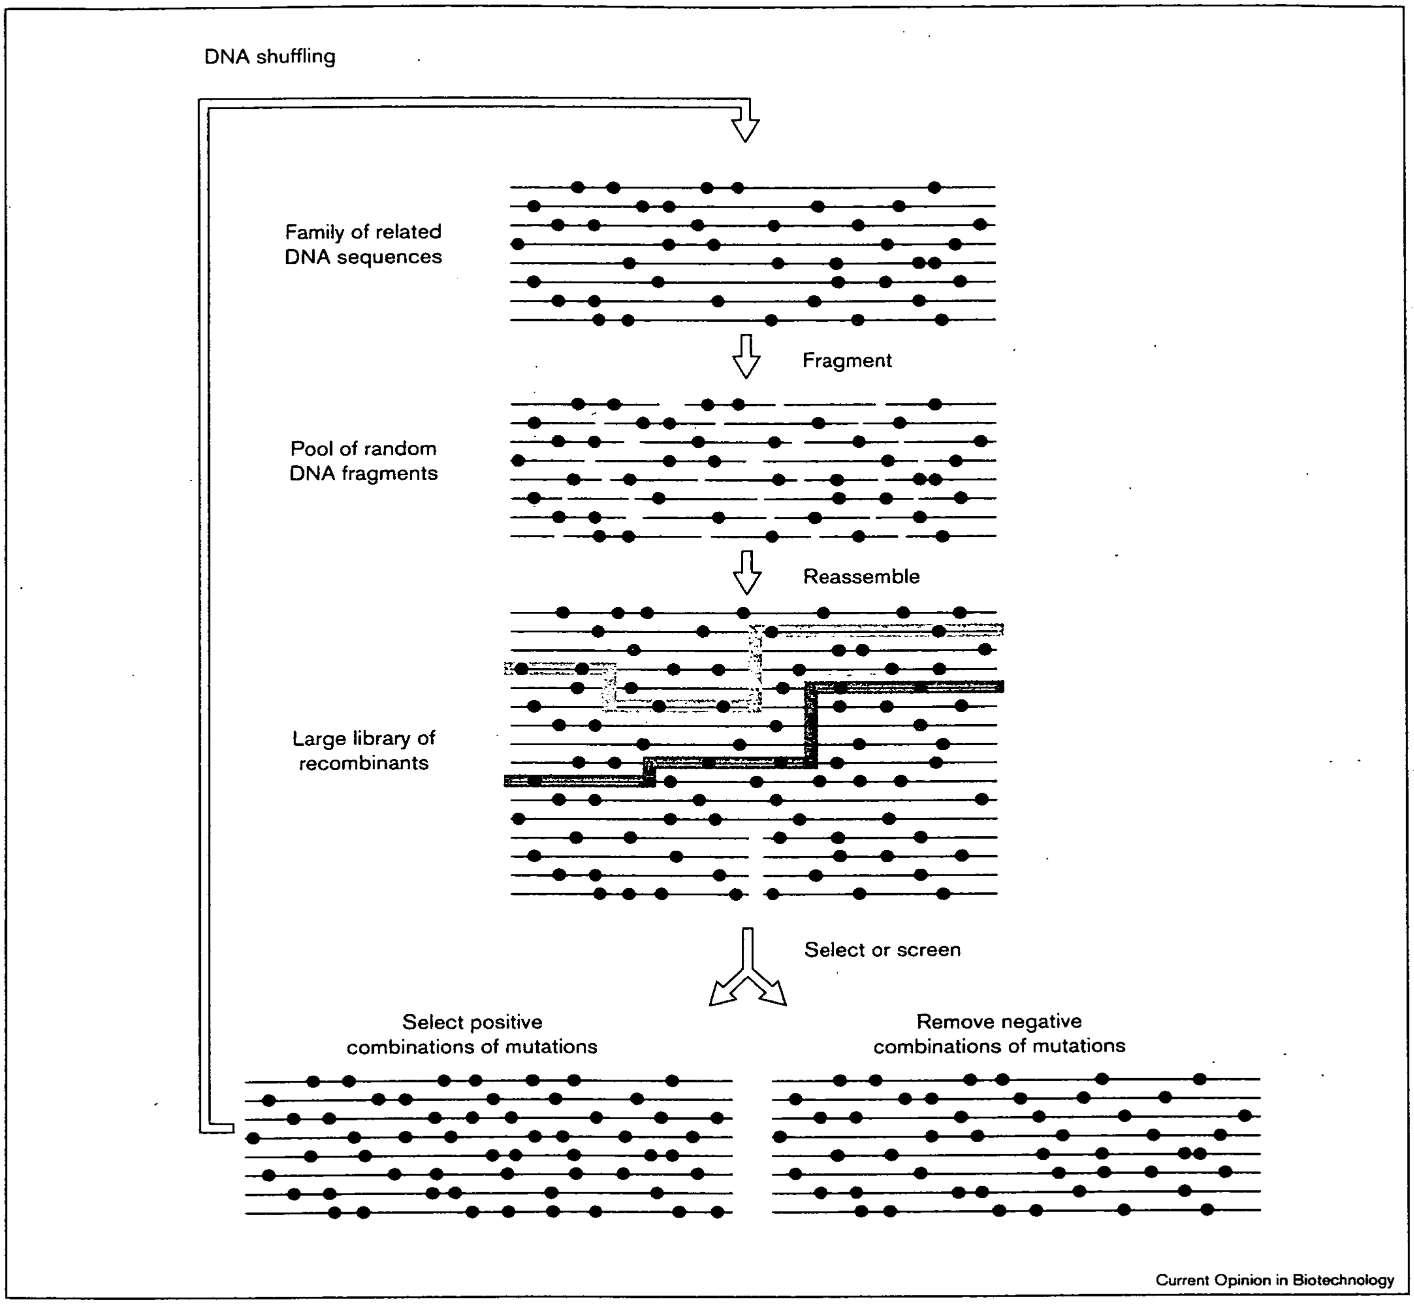
We have recently applied DNA shuffling to members of the human α-IFN gene family (85–97% pairwise amino acid identity). Greater than 10^{26} distinct recombinants can be generated from the natural diversity in this gene family (Figure 4a). While no foreseeable library technology will allow an 'exhaustive' sampling of this sequence space, DNA shuffling technology provides a design algorithm with which to selectively breed for IFNs with increased potency relative to naturally occurring IFNs. Typical chimeras produced by DNA shuffling are shown in Figure 4b. Generic high-throughput methods for α-IFN expression and biological assay as fusion proteins on phage have been developed and used for rapid parallel analysis of recombinant IFNs. Phage-displayed recombinants with improved potency on human and murine cells have been obtained (Figure 4).

This generic approach can be applied to improve many pharmaceutical proteins. Proteins with novel activities have been created by directed chimerization of modules from existing pharmaceutical proteins [17,18], a strategy that is likely to be particularly effective with cytokines, which typically act by dimerizing two or more receptor components. As with the rapid evolution of moxolactamase activity by shuffling a cephalosporinase gene family [16••], many new pharmaceutical activities may be discovered through breeding large libraries of chimeric pharmaceutical proteins. Selective breeding using DNA shuffling will allow rapid evolution of pharmaceutical proteins with potent activities from such recombinants, which initially have low levels of the desired activity. Backcrossing of these evolved variants with the wild type genes will allow one to remove functionally neutral changes, thus reducing the immunogenicity of the evolved proteins.

Small molecule pharmaceuticals and industrial enzymes

Microorganisms are widely used for the production of pharmaceutical molecules, such as antibiotics, antifungals, anticancers and immunosuppressives. In many cases, the genes encoding the relevant biosynthetic enzymes are known, often occurring in operons or gene clusters. Rational engineering of these biosynthetic pathways to improve yield or generate analogs is difficult because,

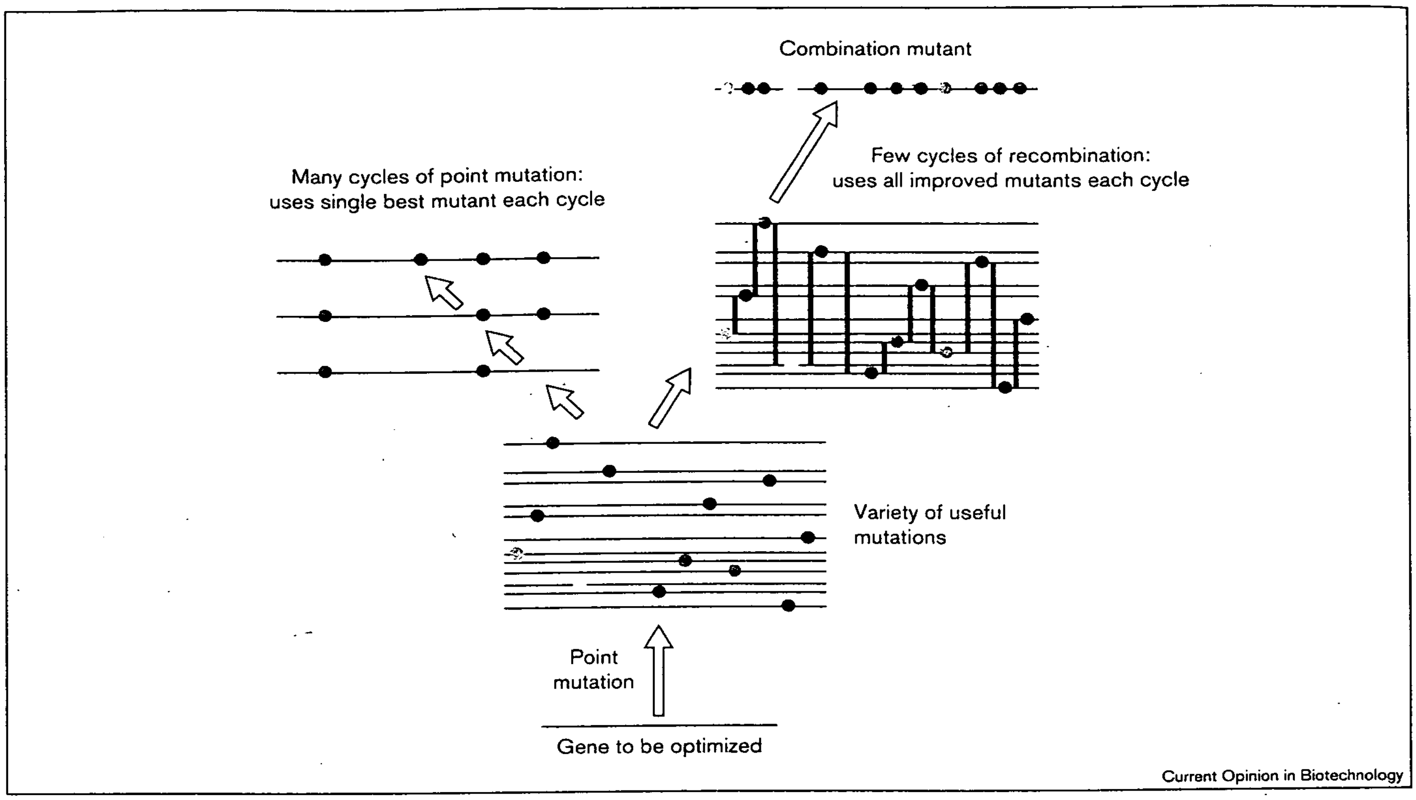
Figure 1



DNA shuffling methodology. The first step of this method is to randomly fragment a population of related genes using DNAse I. This produces fragments of various lengths that, after denaturation, hybridize to form an equal mixture of 5′ and 3′ overhangs. Using PCR techniques, the 5′ overhang fragments can be extended by Taq DNA polymerase – leaving the 3′ overhang fragments unaffected. As a consequence of this extension, the average fragment length increases during each cycle. Recombination occurs when a fragment derived from one template primes a template with a different sequence [13]. Green dots represent beneficial mutations and red dots represent deleterious mutations. The coloured bars indicate recombinations of portions of three parents into recombinant progeny.

in addition to the difficulties of protein engineering, the determination of rate limiting steps in the pathway is laborious and uncertain. DNA shuffling is well suited to the optimization of such pathways because the entire pathway can be treated as the unit for evolution, with no requirements for knowledge of the rate limiting steps or for detailed structure/function analysis of the proteins. Pathways for the detoxification of atrazine (J Minshull, personal communication) and arsenate [19•] have been improved using DNA shuffling (Table 1). Importantly, in these examples no *a priori* knowledge was needed to yield significant improvement. A benzylesterase used

Figure 2



The advantages of DNA shuffling as a sequence design algorithm for evolving complex new gene functions are shown schematically. The coloured dots represent beneficial mutations. The vertical direction represents a generalized measure of fitness (i.e. kcat/Km for an enzyme) with the fitest genes being at the top. Because the frequency of beneficial mutations is generally low relative to deleterious mutation, only single beneficial mutations are generally added in each cycle of random mutagenesis and screening or selection. Hence, procedures that use iterative point mutations must build up beneficial mutations one at a time through many rounds of selection, generally with only the best mutant from any given cycle being pursued. In contrast, DNA shuffling allows one to directly recombine all beneficial mutations from any given round into multi-step mutants with dramatically improved phenotypes.

industrially for deprotecting a precursor of the antibiotic loracarbef has been improved using DNA shuffling ([20]; Table 1). Recombination was shown to be superior to sequential error-prone point mutation for the evolution of this activity [21•]. DNA shuffling has also recently been used to modify the specificity of a tRNA charging enzyme [22], with the ultimate goal of evolving tRNA synthetases that can specifically charge tRNA's with unnatural amino acids incorporated at specific sites.

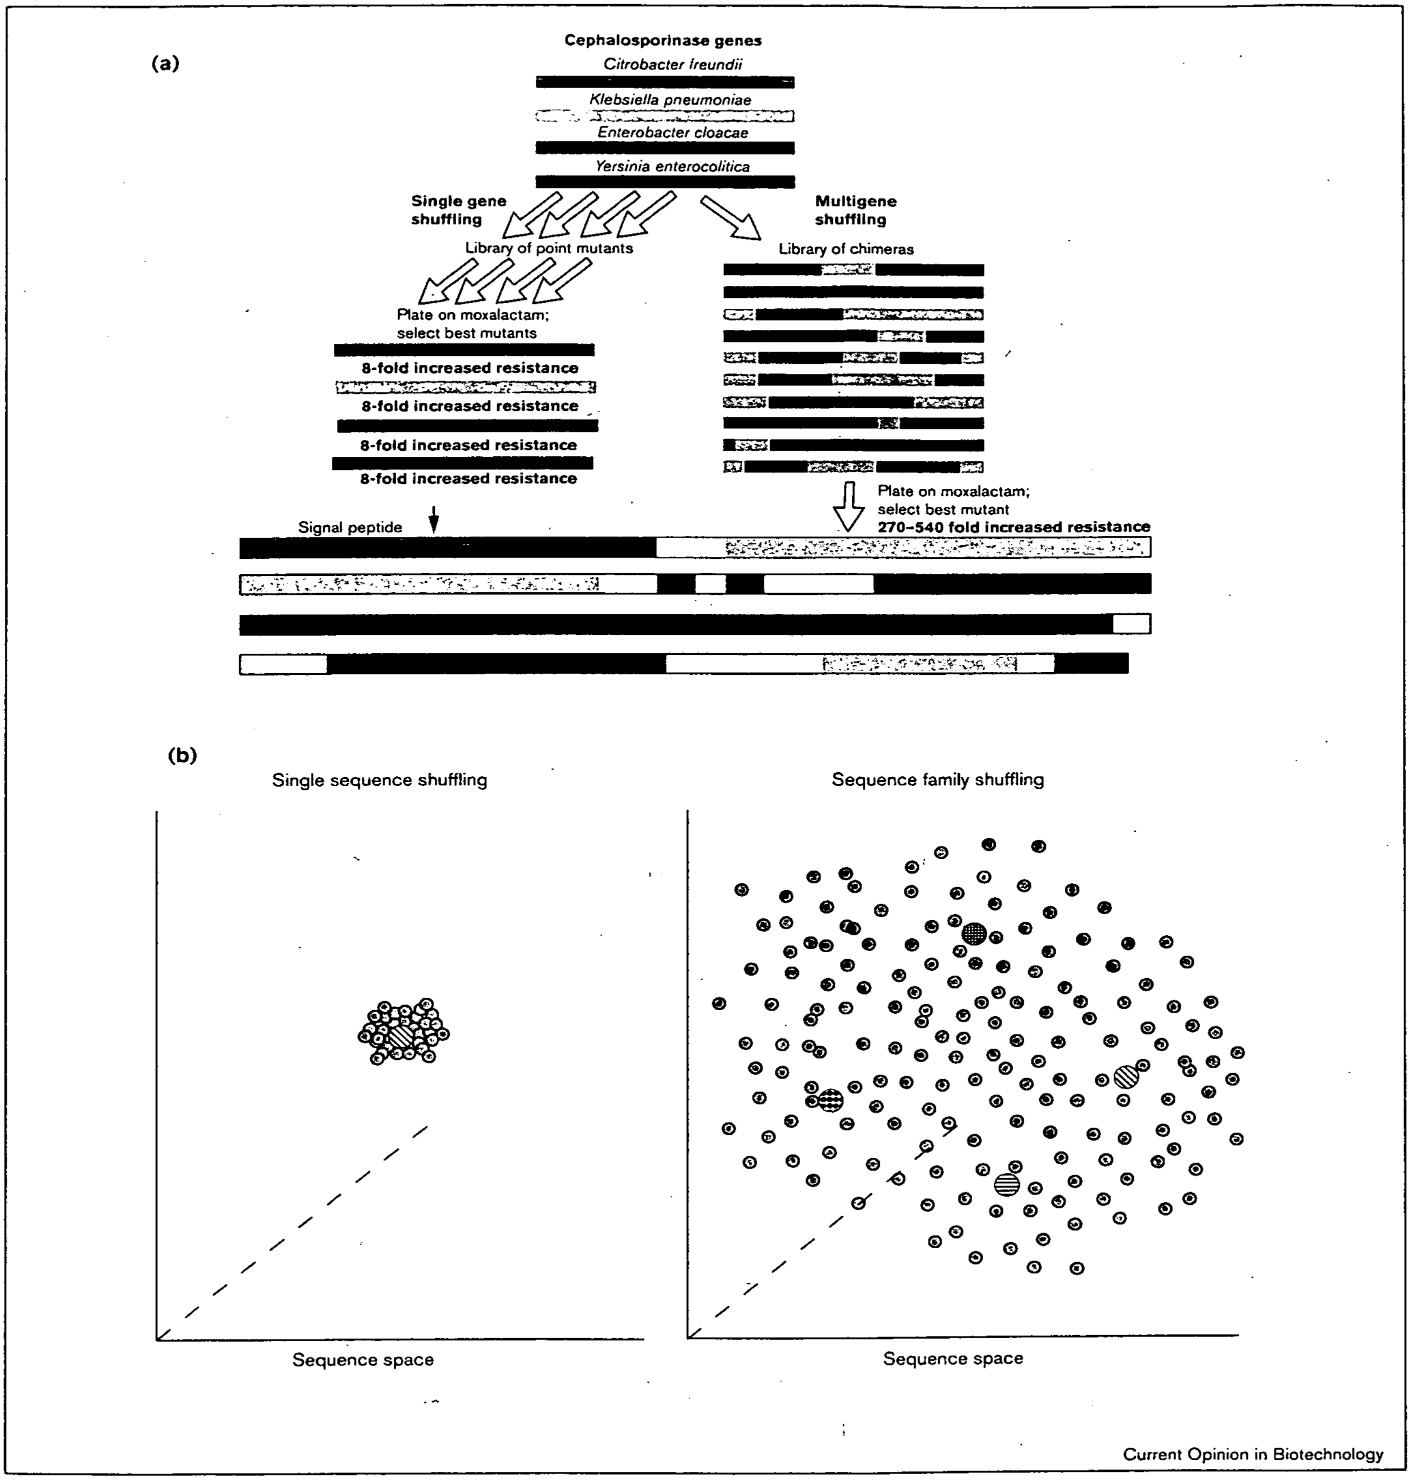
Evolved enzymes will find wide application in the replacement of multi-step chemical reactions required for manufacture of drugs or their precursors by an enzymatic conversion. Most naturally occurring enzymes capable of such valuable conversions require significant modification in activity, specificity, or expression level before they are suitable for large scale drug manufacture. DNA shuffling provides an important tool for the optimization of such enzymatic conversions.

Evolved viruses for pharmaceutical applications

The full length genomes of many viruses are in the range of 5–15 kilobases (kb), a size range that can be readily handled by current DNA shuffling methods (Table 1). Our ability to clone and sequence the wealth of natural viral isolates far outstrips our molecular understanding and our ability to rationally manipulate them. Three wild-type strains of human papilloma virus have been successfully shuffled (D Apt, personal communication). The biological properties of this library of recombinants are currently being investigated. This approach has potential for the evolution of human papilloma virus to overcome the blocks to growth in transformed fibroblasts, and thus be able to grow in readily manipulated tissue culture systems for drug screening.

Adenovirus is widely used as a gene therapy vehicle. Over 100 naturally occurring serotypes with differing

Figure 3



(a) The strategy and results from shuffling four homologous cephalosporinase genes are shown schematically. Single gene shuffling resulted in eightfold increased resistance to the antibiotic moxolactam, whereas shuffling the gene family gave a 270–540-fold increase in resistance in a single step [16]. **(b)** Evolution starting from a single gene is schematically contrasted with evolution based on shuffling a homologous gene family. The axes denote a generalized sequence space. Shaded dots indicate particular sequences present in a given library. Hatched dots represent sequences that are more fit than the best parental molecule. Greater distance indicates greater sequence divergence. Family shuffling results in a relatively 'sparse' sampling of sequence space with relatively few individuals that are highly similar to the parental molecules and many individuals that are very divergent from the parents.

Table 2

Development of novel human therapeutics through molecular breeding technology.

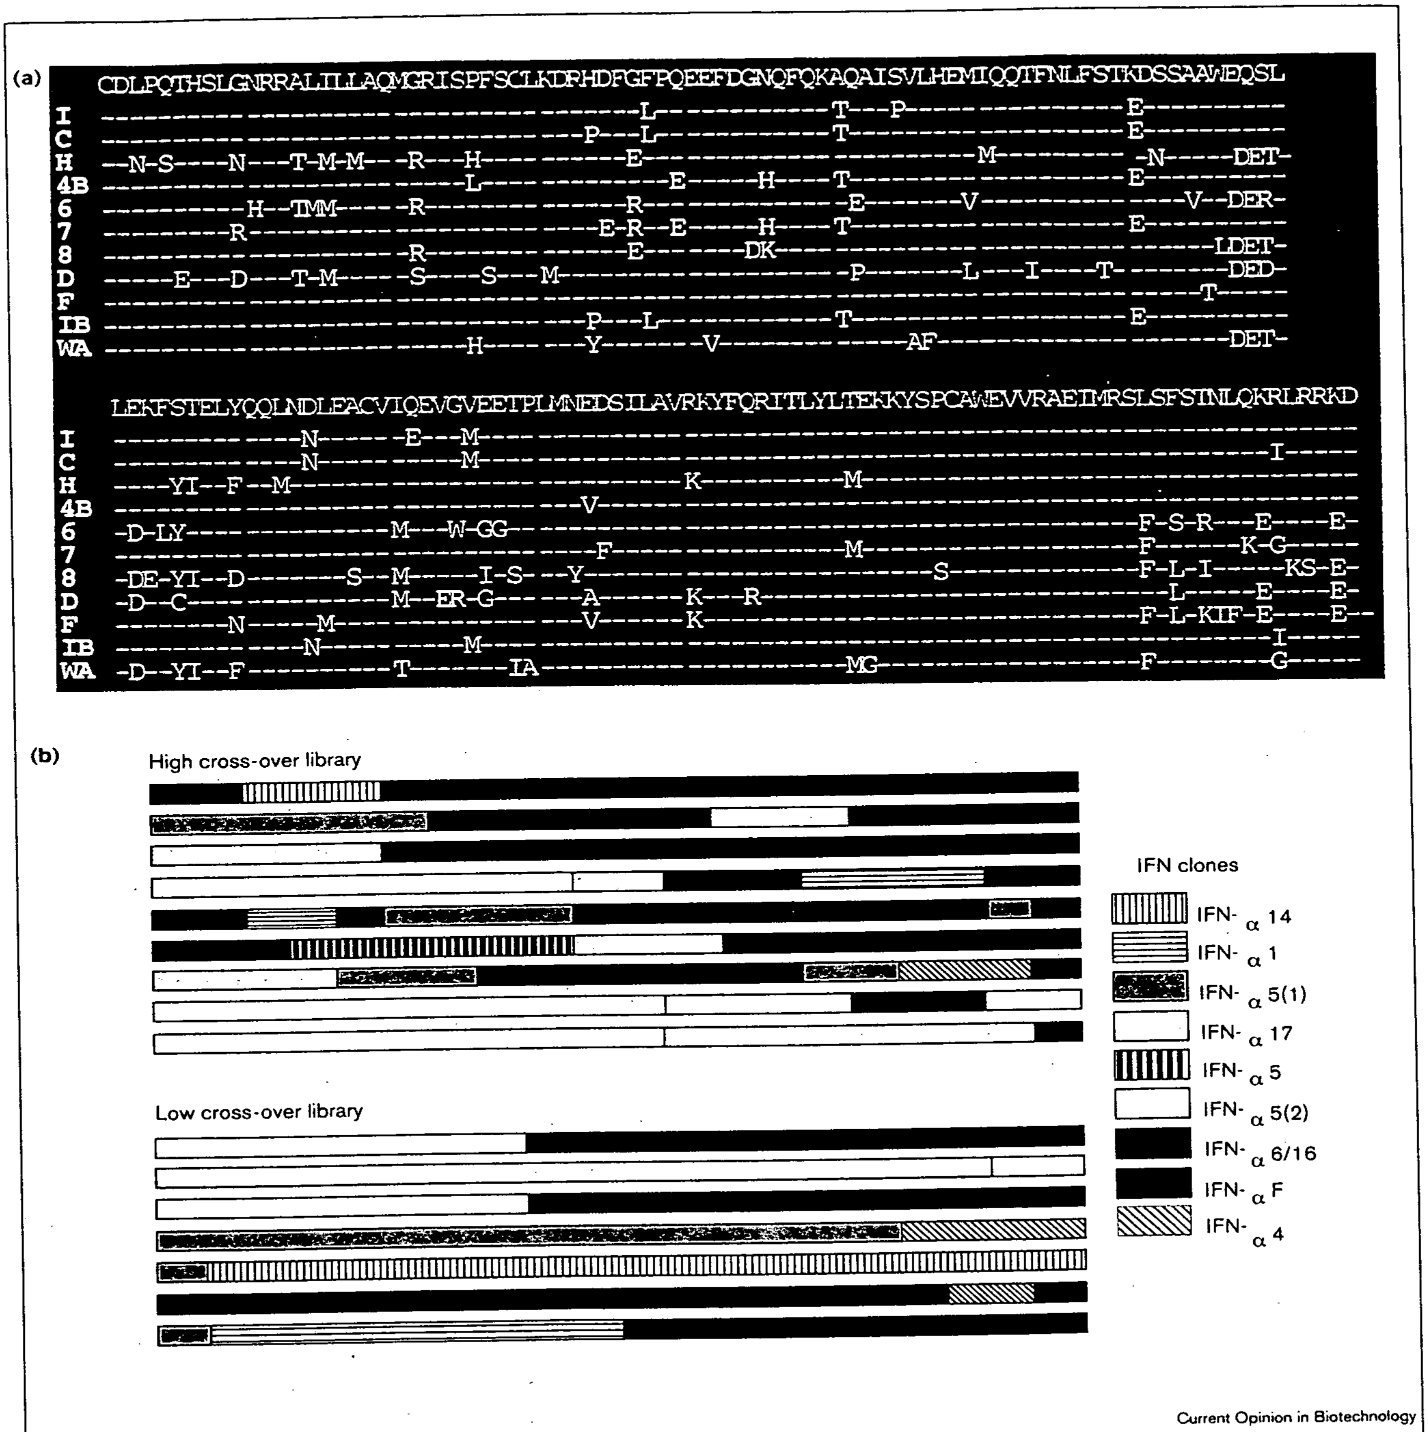
Therapeutic area	Size of shuffled DNA	Novel properties for screening or selection
Protein pharmaceuticals	1–5 kb	Receptor selectivity Improve agonist/antagonist activity Novel agonist/antagonist activity Toxicity Optimal expression in desired host – shuffle the expression vector and/or protein gene Plasma half-life/protein and cell binding
Small molecule pharmaceuticals	1–5 kb	Manufacturing enzymes: desired properties for enzymes that replace chemical synthetic steps in drug manufacture (pH and temperature optimization, solvent tolerance, etc.)
	1–20 kb	Natural products: generation of drug analogs/new structures by shuffling entire pathways – screen for pharmaceutical activity Strain improvement
Gene therapy	1–20 kb	Vectors Transgenes
DNA vaccines	1–20 kb	Plasmid properties of promoter strength, tissue tropism and cell entry, plasmid stability Antigen shuffling to optimize immune response Shuffling to improve immunostimulatory sequences Qualitative nature of immune response (shuffling cytokine gene cassettes)
Recombinant protein vaccines	1–20 kb	Optimal expression in desired host – shuffle the expression vector and/or the protein gene while selecting for retention of recognition by protective mAbs Shuffling to generate family of immunogens for antigenically variant targets
Viral vaccines	1–20 kb	Enable viral growth/optimize yield in desired cell for manufacturing Select for retention of desired properties when viral families are shuffled – neutralization assay, antibody effects Select for attenuation (growth rate, temperature, retention of some properties) Select for optimal expression of recombinant antigen(s) genes in viral vaccine vectors
Evolved viruses	1–20 kb	Evolve to grow in animal models such as mice Evolve viruses to grow in easily manipulated tissue culture systems

tropisms are known. The fiber and penton genes of adenovirus are the major determinants of tissue tropism, as they are responsible for cell adhesion. The pentons of adenoviruses interact with cellular integrins [23] and the fibers with cellular receptors, one of which has been newly identified [24]. Evolved adenoviral variants which could be selectively targeted to particular cell types would be of great utility for gene therapy and vaccine delivery vectors. The penton and fiber genes of various adenovirus serotypes have been shuffled (S Liu, personal communication) and this approach may allow one to evolve mutant adenoviral vectors with desired cell and tissue tropism.

Murine leukemia virus (MLV) is a retroviral vector that has received much attention as a gene therapy vehicle. As with adenovirus, there are <100 naturally occurring strains, whereas only a single MLV strain is being developed for gene therapy applications (Moloney MLV). The envelopes of 15 MLV strains have been shuffled and viruses are being selected for improved tropism, titer, stability and gene expression properties (N Soong, personal communication).

HIV-1 poses a major threat to human health which is increasing because of the growing viral load worldwide, the high rate of evolution of this pathogen, and the concomitant evolution of associated opportunistic pathogens in HIV-1 infected individuals. There is currently no practical animal model in which to test the multitude of antiviral drugs or vaccine strategies [25]. Work is beginning on the genetically engineered animal models to support replication of HIV-1 (D Littman, M Goldsmith, personal communication), but no replication has yet been observed in these hosts. It is clear from viral phylogenetic trees that lentiviruses can evolve the ability to grow in new species and it is clear that recombination plays a major role in the natural high rate of evolution of lentiviruses [20]. DNA shuffling provides a powerful new tool with which to accelerate the adaption of viruses to grow in laboratory animal hosts. Recombination is believed to be of great importance for the naturally high rate of evolution of retroviruses [26]. Laboratory animals have been engineered with the human HIV-1 receptor and co-receptor genes (D Littman, personal communication). DNA shuffling is being used to recombine entire genomes and individual genes of natural HIV-1 isolates to accelerate the adaptation of HIV-1 to grow in these engineered animals (P Patten and N Landau, unpublished data). We anticipate that the adaptation of HIV-1 to replicate in a laboratory animal will open up many fertile avenues for drug and vaccine discovery on this important human pathogen. Shuffling of natural diversity to create large libraries of chimeric viruses is a general approach that can be applied to other viruses, such as the hepatitis B

Figure 4



(a) Human α-interferon diversity. The sequences of eleven natural human α-IFN sequences are shown [29]. Consensus α-IFN is given at the top. Dashes indicate identity to consensus. The number of distinct recombinants that can be generated by shuffling these eleven genes is 3×10^{26}. This number is calculated by multiplying the number of different amino acids observed at each polymorphic site ($2^{56}\times3^{15}\times4^{4}=3\times10^{26}$). **(b)** Sixteen representative recombinant α-IFNs derived by shuffling eight natural human α-IFN genes are shown schematically (P Patten, unpublished data). The high crossover and low crossover libraries were generated by shuffling 20–50 bp or 50–100 bp fragments, respectively. The DNA shuffling was done essentially as described in [16]. The shuffled IFNs were expressed as fusions to gene III on bacteriophage M13 and screened for antiproliferative activity using Daudi cells. Phage displayed αIFN–MAX4 (high crossover library, fourth from the top) is 40-fold more active in a Daudi antiproliferation assay than IFN2α and twofold more active than consensus 1 IFNs displayed on phage.

virus and hepatitis C virus, for the purpose of producing domesticated forms of these viruses (i.e., easier to handle in the laboratory) for vaccine development and drug screening on variants that can readily be grown in tissue culture systems.

Vaccines

Development of effective vaccine technologies has stimulated renewed government emphasis and interest from pharmaceutical researchers. DNA vaccines are particularly attractive because of their relatively low cost and the feasibility of rapid generation of diverse variant vaccines containing evolved promoters, immunostimulatory sequences, cytokines, etc., for comparison testing [27]. For example, assays for selection of DNA vaccines with improved promoter activity, immunostimulatory sequences, enhanced expression levels or cell tropism can be developed to produce second generation DNA vaccine plasmids. Viral vaccine vectors can be enhanced by DNA shuffling to give desired properties of tropism, stability and expression level. The promise of this new technology notwithstanding, existing human vaccines rely on live or killed whole organisms or components purified from whole organisms. We envision opportunities for DNA shuffling as a tool for increasing the efficiency and success rate of the development of novel whole organism, viral, bacterial and recombinant protein vaccines. Pathogenic viruses can be subjected to DNA shuffling followed by selection for desired attenuation properties while retaining the immunogenicity required for a vaccine. Viruses that would serve as excellent vaccine vectors or as vaccines but which cannot be manufactured to sufficient titer in manufacturing cell lines, can be shuffled and selected for improved titre to create new commercial opportunities. Recombinant proteins that are known to be excellent vaccine immunogens but which cannot be manufactured in appropriate yield or in suitable host systems can be shuffled and screened to solve such expression problems, while co-selecting for retention of necessary epitopes. These and other valuable opportunities for application of DNA shuffling technologies in vaccinology are summarized in Table 2.

The impact of genomics

The rapid rate of increase in the availability of known gene sequences and our ability to manipulate them in cloned form greatly exceeds our understanding of these genes and our ability to engineer these sequences based on rational models. Sequence information from informatics databases can readily be converted into functional DNA clones given tools such as PCR, synthetic DNA and methods for the rapid assembly of genes from synthetic DNA [28].

Shuffling of natural diversity to explore the sequence space defined by shuffled homologues is a demonstrably powerful strategy for accelerated evolution of biological molecules with novel activities ([16]; Figure 3). We expect the dramatic success seen with family shuffling of cephalosporinase genes to be repeated in many other systems in which homologous genes are recombined. The explosion of DNA sequences available on the internet provides a rich, diverse and rapidly expanding supply of molecular breeding stock. DNA shuffling is a general and natural algorithm for functionally exploiting this natural diversity, with minimal requirements for *a priori* genetic or biochemical characterization to guide this exploitation.

Conclusions and future directions

In order to unlock desired biologically active sequences from the potential diversity present in an organism's gene pool, it is of great importance to understand which evolution algorithms are the most effective. Point mutation techniques, such as error-prone PCR and repeated oligonucleotide directed mutagenesis, search sequence space by creating libraries of randomly mutated molecules. In contrast, DNA shuffling exchanges large functional blocks of sequence containing previously selected mutations to search for the best candidate molecules, thus mimicking and accelerating the process of sexual recombination. We expect that, just as recombination has played a major role in the evolution of life, DNA shuffling will play a central role in the development of applied molecular evolution technologies and will prove indispensable for bringing existing biological diversity into the service of human health care, and agricultural and industrial chemical needs.

Codon usage tabulated from the GenBank genetic sequence data

Ken-nosuke Wada[1], Yoshiko Wada[2], Fumie Ishibashi, Takashi Gojobori and Toshimichi Ikemura
National Institute of Genetics, Mishima, Shizuoka-ken 411, [1]Chukyo University, School of Computer and Cognitive Sciences and [2]Niigata University, School of Medicine, Japan

Codon usages in 22361 genes can be analyzed using the nucleotide sequence data obtained from the GenBank Genetic Sequence Data Bank (Release 69.0, Sept.,1991). The database is called as the CUTG Database (1–4), and is distributed on EMBL CD-ROM (December 1991; CODON by Wada et al.) as a member of NAR Sequence Supplement Databases (5). The CUTG codon database is also available for on-line access to DDBJ (DNA DATA BANK OF JAPAN): Please, contact with DDBJ (Mail Address; ddbj@ddbj.nig.ac.jp).

Files named as ***.CODON.69 list the codon use in each of gene registered in the GenBank Sequence files (gb***.seq). The LOCUS names given in the GenBank were used for designating individual genes, and the SHORT DIRECTORY of the GenBank Short Directory File is presented for defining each LOCUS name analyzed here (see ***.SDR.69).

To reveal the characteristics of the codon use of a wide range of organisms, as well as viruses and organella, the frequency (per one thousand) of codon use in each organism for which more than 20 genes are available was calculated by summing up numbers of codon use (***.total.69); Table 1 of this paper. The number of genes summed for each organisms is given in the row designated as GENES, and the total codon number thus summed is given at the bottom row. Names of the organisms are listed in the SPECIES FILE (Table 2). Amino acids are added simply according to the universal codon table.

METHODS

In selecting protein coding sequences we relied on the FEATURES tables of the GenBank, and only complete genes, starting with an initiation codon and ending with one of stop codons, were used in the analysis (see REFERENCES for details). In the GenBank, a group of consecutive genes whose entire region had been sequenced were registered under one LOCUS name. To distinguish the different genes belonging to a single LOCUS, symbol # followed by a number is added after the LOCUS name; the numbers represent the order of the peptides registered in the FEATURES of the GenBank. When introns of a gene have not been completely sequenced, some of its exons are registered in separate entries (LOCUS) in the GenBank. These exons belonging to the same gene but having different LOCUS names were combined, and the LOCUS name of the last exon followed by symbol * was given to the gene thus combined. The order of the codons in the table is the same as the previous compilation (see the CODON_LABEL file or REFERENCES).

ACKNOWLEDGMENTS

The authors are very grateful to Dr. S. Osawa (Nagoya Univ.). This work was supported by grant-in-aid for scientific research from the Ministry of Education, Science and Culture of Japan (No. 01656004).

Fast and sensitive multiple sequence alignments on a microcomputer

Desmond G.Higgins* and Paul M.Sharp

Abstract

A strategy is described for the rapid alignment of many long nucleic acid or protein sequences on a microcomputer. The program described can handle up to 100 sequences of 1200 residues each. The approach is based on progressively aligning sequences according to the branching order in an initial phylogenetic tree. The results obtained using the package appear to be as sensitive as those from any other available method.

Introduction

In the recent literature on biological sequence analysis, at least a dozen methods for performing multiple alignments of nucleic acid or protein sequences have been described [e.g. Bains (1986), Sobel and Martinez (1986), Barton and Sternberg (1987), Feng and Doolittle (1987), Santibanez and Rohde (1987), Taylor (1987)]. The motivation for this effort has been the need for the automatic alignment of three or more sequences for the purposes of evolutionary or structural comparisons or for attempting to demonstrate similarity between sets of sequences. In this paper, we describe a strategy which we believe offers the best combination of speed and sensitivity available for any multiple alignment method. We offer a program which can perform multiple alignments of up to 100 sequences of maximum length 1200 residues on a microcomputer in a reasonable amount of time. We judge the program to be 'sensitive' because the results obtained are very difficult to improve by eye.

The strategy we use is essentially that of Feng and Doolittle (1987) adapted for use on microcomputers. The general approach is to progressively align groups of sequences according to the branching order in a hypothetical phylogenetic tree, with gaps that occur in earlier alignments being preserved through later stages. At each alignment stage, a two-sequence alignment algorithm, such as the dynamic programming method of Needleman and Wunsch (1970), is used. For two sequences, the Needleman and Wunsch algorithm gives an alignment that is guaranteed to be optimal for a given set of scoring rules (i.e. weights for aligned residues and penalties for gaps). When this method is used to align two sets of sequences, the score at each position in the alignment is taken from the average score for each residue in one set compared against each residue in the second set. Any gaps introduced into either set of sequences are scored as single gaps. The main difficulty in using this approach on a microcomputer arises from the excessive memory requirements of the Needleman and Wunsch (1970) method—memory usage is proportional to the square of the average sequence length.

In a previous paper (Higgins and Sharp, 1988) we described a strategy for the very rapid multiple alignment of large numbers of sequences on a microcomputer. This method also comprised a progressive approach, using the fast, but approximate, two-sequence alignment method of Wilbur and Lipman (1983). While this approach is extremely rapid and economical with core memory, it works well only for closely related sequences. We did not consider using the exactly optimal method of Needleman and Wunsch (1970) for the progressive alignments because of the excessive memory requirements. However, a recent paper by Myers and Miller (1988) demonstrates how to achieve exactly optimal alignments of two sequences where memory usage varies only linearly with sequence length, without making use of bit packing or secondary disk storage. Thus, a progressive series of alignments of larger and larger groups of sequences, using the method of Myers and Miller (1988) for each alignment, is the key to the current approach.

System

The program described in this paper was written in standard FORTRAN 77 and compiled using the Microsoft FORTRAN compiler, version 4.0. Program performance was tested on an IBM AT compatible microcomputer, running at 10 MHz with no maths coprocessor, 640 kbytes of memory and a hard disk. This program (CLUSTAL4) is an extension to the package described in Higgins and Sharp (1988). Copies of the executable files, documentation and test data files will be sent on request. Please send three 5.25 inch floppies formatted to 360 kbytes, or one high density 5.25 inch floppy formatted to 1.2 Mbytes.

Algorithms

The program takes, as input, a dendrogram produced by applying the UPGMA method (Sneath and Sokal, 1973) to a matrix of similarity scores between all pairs of sequence to be aligned. The similarity scores are calculated as the number of exactly matched residues in a Wilbur and Lipman (1983) align-

Department of Genetics, Trinity College, Dublin 2, Ireland
**To whom correspondence should be addressed*

ment between two sequences, minus a fixed penalty for every gap. For short sequences, several similarity scores per second can be calculated on a microcomputer using the package described in Higgins and Sharp (1988).

The sequences are then aligned in groups corresponding to the branching order in the dendrogram. The alignments are carried out using the method of Myers and Miller (1988), adapted for use in a multiple alignment context. Myers and Miller took the distance minimizing algorithm of Gotoh (1982) and applied a 'divide and conquer' strategy (attributed to Hirschberg, 1975) to give alignments in linear space; as a consequence memory usage is linearly related to sequence length. Briefly, the method is based on finding the optimal mid-point of an alignment. When this is found, the matched symbols (two aligned residues, or one residue opposite a gap) are part of the final alignment. The rest of the alignment is found by recursively finding optimal mid-points on either side of the initial mid-point. In this context, the optimal mid-point can be defined as the aligned symbols at the centre of the optimal alignment. The centre is taken to be half way along one sequence.

Two modifications were needed to adapt the Myers and Miller algorithm for our program. Firstly, all real number operations were converted to using 2-byte integers. On a 16-bit microcomputer without a maths chip, this increases the speed of each alignment by a factor of 30. Indeed the speed approaches that described in Myers and Miller for their program running on a VAX 11/780. Secondly, the scoring system was modified to allow all residues at a given position in each group of sequences to contribute to the alignment scores. For proteins, we use the log-odds amino acid similarity matrix of Dayhoff (1978) to score aligned residues. The similarity matrix was rescaled to give positive integer weights between 0 and 25 and then converted to a difference matrix by subtracting each value from 25. Thus two aligned tryptophans have the lowest distance (0) while a cysteine aligned with a tryptophan has the largest distance (25). For nucleic acid sequences we use a three-tier weighting system where identical residues have zero distance, transitions have a distance of 5 and transversions have a distance of 10. A variable gap penalty is used; a fixed penalty is added to the alignment distance for every gap and an extra penalty is added for every item in the gap. Gaps that are introduced into a pre-aligned group of sequences are scored as single gaps. Both of these penalties can be specified at run time.

In order to calculate the alignment scores between two clusters of sequences, the gaps that are already inserted in the two clusters (from earlier alignment stages) are treated as being fixed. Thus, each cluster may be thought of as a single sequence,

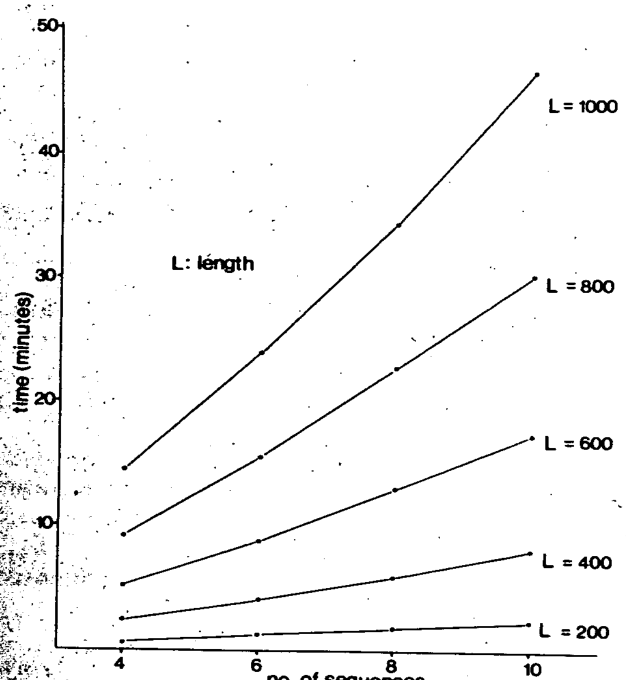

Fig. 1. Times required for the multiple alignment of different numbers of sequences of different lengths. Each curve represents the times for truncated fragments of a given length, L; this example used the HIV pol protein. Times for calculating the similarity matrices or dendrograms (maximum of <3 min) are not included.

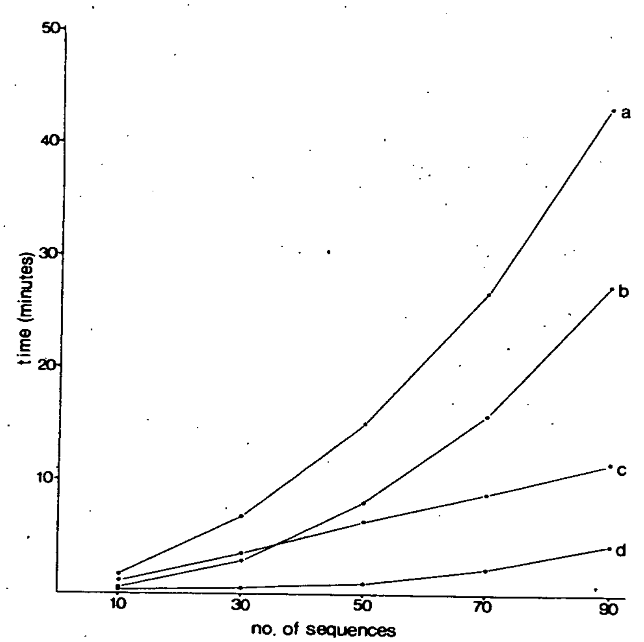

Fig. 2. Times for aligning different numbers of sequences. This example used globin sequences (alphaglobins, betaglobins and myoglobins) each truncated to 140 residues. The four curves show times for different parts of the multiple alignment process: (a) total time, including calculation of similarity matrix and dendrogram, (b) calculation of similarity matrix, (c) multiple alignment, (d) construction of UPGMA dendrogram.

where the residues at each position are the 'average' residues at that position in each of the sequences represented by the cluster. In order to calculate the weight between a position in one cluster and another position in the second cluster, one takes the arithmetic average of all the pairwise weights between each residue in one cluster versus all of those in the second. For two clusters with K and L sequences each, this involves taking the average of K times L weights at each alignment position. This becomes very time-consuming with many sequences, but can be speeded up by pre-calculating the weight of each position in each cluster versus each possible residue.

Results and discussion

The speed of the program can be demonstrated by aligning different numbers of sequences of different sizes. We find that the speed is almost totally independent of the characteristics of the sequences, apart from length. This was also noted by Myers and Miller (1988) for their two-sequence alignment program. Figure 1 shows the times required for a series of multiple alignments of sequences from 200 to 1000 amino acids in length. One expects the alignment times to vary with the square of the sequence lengths and a visual inspection of the figure confirms this. The time required to align different numbers of sequences varies approximately linearly. A slight departure from linearity is evident with the longer sequences. This confirms the effectiveness of our stategy of pre-calculating the weights at different positions in each cluster. The times required for calculating the initial similarity matrices and construction of the dendrograms are not shown. These only need to be calculated once for any multiple alignment. The slowest dendrogram to construct was that for the ten 1000 residue sequences. This took under 3 min.

Figure 2 shows the times required to align from 10 to 90 sequences of 140 amino acids each. In this case the times for each of the various calculations are shown. The similarity matrices and dendrograms were constructed using the programs CLUSTAL1 and CLUSTAL2 (Higgins and Sharp, 1988) respectively. For large numbers of sequences, the calculation of the initial similarity matrix is the dominant time-consuming factor. For 90 sequences, this requires the calculation of 4005 values. Nonetheless, the times involved are quite practical on a microcomputer.

The sensitivity of the program is more difficult to demonstrate. Our basic criterion in determining sensitivity is to assess the ease with which the resulting alignments can be improved by manual adjustment. By this criterion, we find the results of our program to be excellent. In this respect, the program can be used confidently to replace the usual manual alignment of sets of closely related sequences for publication. Of greater scientific importance is the usefulness of the program for aligning regions of homologous secondary structure or in reconstructing evolutionary events between distantly related sequences. This is more difficult to demonstrate. Barton and Sternberg (1987), Feng and Doolittle (1987) and Taylor (1987) discuss these questions in detail. It is possible that no single method will be ideal for these purposes. As a general observation, we find the alignments produced by our program to be at least as good as those produced by each of the above authors.

Summary. A progressive alignment method is described that utilizes the Needleman and Wunsch pairwise alignment algorithm iteratively to achieve the multiple alignment of a set of protein sequences and to construct an evolutionary tree depicting their relationship. The sequences are assumed a priori to share a common ancestor, and the trees are constructed from difference matrices derived directly from the multiple alignment. The thrust of the method involves putting more trust in the comparison of recently diverged sequences than in those evolved in the distant past. In particular, this rule is followed: "once a gap, always a gap." The method has been applied to three sets of protein sequences: 7 superoxide dismutases, 11 globins, and 9 tyrosine kinase-like sequences. Multiple alignments and phylogenetic trees for these sets of sequences were determined and compared with trees derived by conventional pairwise treatments. In several instances, the progressive method led to trees that appeared to be more in line with biological expectations than were trees obtained by more commonly used methods.

Key words: Multiple sequence alignments — Evolutionary trees

Introduction

The evolutionary relationships of sets of protein (or nucleic acid) sequences are commonly depicted in the form of trees (Fitch and Margoliash 1967; Dayhoff et al. 1972; Moore et al. 1973; Sankoff et al. 1982; inter alia). Indeed, the digital nature of sequence data makes them more amenable to such treatment than is the case with many more qualitative biological characters. Most current schemes for constructing trees from sequences use a simple difference matrix, the elements of which are assembled by performing pairwise comparisons of all the sequences under study (Fitch and Margoliash 1967). A topology is found by classifying the sequences according to their differences, which ought to be a reflection of the evolutionary distances among them. For the most part, the principle of parsimony is rigorously adhered to, and the best trees are thought to be those that can account for the extant sequences by the smallest number of genetic events. The two important features of a tree are its topology, or branching order, and its branch lengths, which ought to be proportional to the true evolutionary distances.

In principle, the construction of an evolutionary tree based on sequence data ought to be a simple matter: all one has to do is cluster the sequences according to their similarities. In practice, uncertainties and ambiguities concerning both the topology and branch lengths are common, and enormous effort is often expended in finding the "best tree" (e.g., Fitch 1977; Penny and Hendy 1986). Finding the correct tree should depend on assembling a matrix that best describes the differences among the sequences, and this depends, in turn, on properly aligning the sequences (Hogeweg and Hesper 1984). The alignments can be obtained either by schemes that maximize similarity (Needleman and Wunsch 1970) or with those that minimize differences (Sellers 1974). If a similarity scheme is used, the scores must be transformed appropriately into measures of distance.

Offprint requests to: Da-Fei Feng

Ordinarily, alignments of either type are performed pairwise. The problem is that when the various paired alignments are grouped, they are seldom consistent one to another. Thus, when sequence A is paired with sequence B, gaps may appear at various locations, but when either A or B is aligned with a third sequence, C, the arrangement of gaps may be entirely different. Heretofore, this problem has been circumvented by making a multiple alignment of all the sequences by the judicious shifting of the sequences as needed to minimize differences ("eyeball" alignment).

The flaw in the approach is that these multiple alignments have, like pairwise alignment schemes before them, been subject to rigorous attempts at parsimony. Obviously, the closer two sequences resemble each other, the more confidence one has in the alignment. But in most multiple alignment schemes where maximum parsimony is sought, no distinction is made with regard to the confidence one has in a particular pairwise alignment. It seems to us folly that a gap should be discarded in an alignment of two closely related sequences merely because an alignment with some distantly related sequence might be improved.

To this end, we have devised a scheme of progressive sequence alignment that has a higher intrinsic regard for recent events than for distant ones. It is still based on a maximization of similarities, but it follows the simple rule "once a gap, always a gap." It is able to accomplish this by inserting neutral elements into sequences once gaps have been established. The sequences are aligned progressively, beginning with the most similar pair and continuing with the addition of the next most similar sequence or set of sequences. The difference scores obtained from the final alignment of all sequences are then used to construct the evolutionary tree. Ambiguities may still arise, of course, since the preliminary matrix of similarities (or differences) based on pairwise comparisons will often include what we call "better but less reliable" scores. These can be sorted out by testing alternative trees. Because it is impractical to consider all possible pairwise orders, we have adopted an effective compromise whereby reasonable alternative arrangements are explored progressively.

In this paper we describe the details of the method and apply it to several groups of protein sequences. Trees constructed by this approach can differ significantly from those assembled by traditional schemes, but they are often in accord with what might be expected on the basis of organismic phylogenies. The method has the added virtue of providing multiple sequence alignments quickly and simply by completely objective criteria.

Methods

Studies were performed on a DEC 11/730 VAX computer with the UNIX (Berkeley 43) operating system. The plotting package for use with a Nicolet Zeta plotter was written by Steve Dempsey of the U.C.S.D. Chemistry Department Computer Center. All utility programs were written in the C programming language (Kernighan and Ritchie 1978). The ensemble of programs dealing with sequence alignment and tree building can be contained by sending a blank magnetic tape to the authors.

Definitions. For purposes of description only, we would like to distinguish between *simple* and *compound* trees. Simple trees are those in which the branching order follows the simple clustering (((AB)C)D) etc., whereas compound trees have subclusters, as in ((AB)(CD)E). *Neutral elements* are simply characters (Xs) that are filled into sequences when gaps occur. They are neutral in the sense that they are invisible to the scoring system used to establish subsequent alignments, which is to say when X is matched with any other residue, the value is equal to zero. *Negative segments* are those internodal connecting distances with negative values that occasionally emerge from Fitch-Margoliash trees when data scatter confounds the segment averaging (or least-squares treatment). *Percent identity* is taken as the number of identities per 100 aligned residues.

Sequences. Amino acid sequences were taken from an updated version of the NEWAT database (Doolittle 1981). Primary references to the nine tyrosine kinase sequences and nine of the globin sequences have been provided in an earlier study (Feng et al. 1985). The additional globins used in the present study are from lamprey (Zelenik et al. 1979) and the bacterium *Vitreoscilla* (Wakabayashi et al. 1986). The superoxide dismutase sequences studied are human (Jabusch et al. 1980), bovine (Steinman et al. 1974), swordfish (Rocha et al. 1984), fruitfly (Lee et al. 1985), maize (Cannon et al. 1987), yeast (Johansen et al. 1979), and photobacter (Steffens et al. 1983).

Pairwise Alignments. The algorithm of Needleman and Wunsch (1970) was used in a three-matrix form (Fredman 1984) and utilized the Mutation Matrix of Dayhoff et al. (1978) in its scoring. The algorithm was actually employed in several slightly different settings. In the first, a program called SCORE aligns pairs of sequences in the conventional way and stores their alignment scores in a table. The similarity scores obtained from the alignments are converted to difference scores by the relationship

$$D = -\ln S_{eff} \times 100 = -\ln \frac{S_{real} - S_{rand}}{S_{ident} - S_{rand}} \times 100$$

where S_{real} is the alignment score itself, S_{rand} is the score obtained with random sequences of the same lengths and compositions, and S_{ident} is the average score of the two sequences being compared when each is aligned with itself. In practice, in these initial pairwise comparisons we use an average value for S_{rand} based on many previous observations (Feng et al. 1985). Inasmuch as this initial set of comparisons is assumed to be imperfect, no precision is lost by the modification, and considerable time is saved by the omission of numerous jumble comparisons. The value used, after normalization to a standard length, was 770, the average random score for numerous comparisons of many different kinds of sequences (Feng et al. 1985).

The Needleman-Wunsch algorithm is used in a second series of alignments in a mode in which gaps are concurrently filled with neutral elements. In the main version, DFalign, sequences are aligned successively. Should the tree in question be a com-

pound tree, subclusters are first prealigned with a simpler version of the program called PREalign.

Tree Building. A program based directly on the Fitch and Margoliash (1967) procedure was written in our laboratory by Mark Johnson. The program, BORD, was used to establish preliminary branching orders. Simply put, the smallest difference score is identified and a new matrix constructed that contains the average distances between members of the first pair and remaining members of the set. The procedure is repeated until all scores have been incorporated. A second program, BLEN, was used for determining branch lengths of the final tree. This program employs a least-squares approach as described by Klotz and Blanken (1981). In the event that a tree contains one or more "negative segments," the "nearest alternative" trees are considered and their scores compared. *Nearest alternative* trees are those in which the branches immediately adjacent to a negative segment are switched. The program TREEplot, also written by Mark Johnson, puts the data in an appropriate form for the Zeta plotter in order that dendrograms can be issued directly.

Outline of the Progressive Method

Pairwise Alignments

For n sequences, the number of pairwise alignments required for the initial matrix amounts to $(n - 1) \times n/2$. To this end, a simple UNIX shell program was constructed for running each comparison serially with the program SCORE; the resulting difference scores are automatically stored in a suitable file.

Identification of Most Closely Related Pair

The program BORD takes the output from SCORE and establishes a preliminary order of the sequences. The program BLEN uses the difference matrix from the SCORE program combined with a simple "connectivity table" to give branch lengths; the connectivity table merely puts all the connecting segments in tabular form. BLEN is only used at this point if trees based on pairwise comparisons are going to be prepared. The BORD program reveals whether or not the starting tree is simple or compound. In the case of compound trees, subclusters are prealigned with the program PREalign, which aligns the cluster and fills the gaps with neutral elements (Xs).

Progressive Insertion of Neutral Elements

The program DFalign, which is the heart of the procedure, is used to generate the multiple alignment. It begins by inserting neutral elements (Xs) in any gaps that occur in the aligned pair with the highest similarity score. After the original pair has been established and the gaps fixed, the next nearest relative or set of relatives is brought in and a new alignment made and a score determined. The key to this alignment is that new gaps can be incorporated into either sequence, but the earlier gaps are preserved. The first ternary arrangement, ABC, is then compared with the alternative BAC, the higher score being used to set the path for the next alignment. Similarly, when the next sequence is brought in, the arrangement ABCD is scored and compared with ABDC. Prealigned subclusters are maintained as separate units, however. The procedure is continued until all sequences have been incorporated.

Scoring the Final Alignment

The final alignment is scored with a modified regimen that recognizes the fixed nature of the gaps. Moreover, because the gaps are fixed, it is unnecessary to use an alignment program at this stage. Instead, a scoring system is used that measures S_{real} and S_{ident} in the usual way, but that employs a program, SHUFFLE, for determining S_{rand}. SHUFFLE randomizes each sequence numerous times while holding the gaps constant.

Constructing the Tree

The program BORD is used to obtain the new branching order and the program BLEN to determine the branch lengths. If any negative segments result, alternative trees with the branches on either side of the negative segment reversed are constructed and a new set of branch lengths calculated. If negative segments are still present, the alternating procedure is continued until they disappear, although we have not yet encountered a situation where more than one switch was necessary. The program TREEplot is used to produce the final dendrogram. A schematic outine of the programs called from start to finish is present in Fig. 1.

Results

Superoxide Dismutase

The sequences of seven copper–zinc superoxide dismutases—human, bovine, swordfish, fruitfly, maize, yeast, and photobacter—were subjected to a conventional pairwise alignment scheme and a tree constructed by the Fitch and Margoliash (1967) procedure (Fig. 2a). The same seven sequences were then treated by the progressive procedure and a tree generated (Fig. 2b). The trees differ both in branch order and branch length. More to the point, the progressive procedure yields a tree that corresponds to the accepted phylogeny of the organisms, whereas the conventionally generated tree does not.

In fact, the initial tree issued from the ordinary Fitch and Margoliash (1967) treatment had the expected phylogenetic branching order, but contained

a negative segment. When the nearest alternative tree was examined, generated by reversing the branches on either side of the negative segment, the sum of branch lengths was lowered, and a "better tree" with no negative segments emerged (Fig. 2a). The tree contradicts what is known of the evolutionary relationships of the organisms involved, however, in that the branch to the yeast sequence comes off above the branch to the *Drosophila* sequence.

It should be emphasized that the multiple alignment (Fig. 3) used to obtain the final tree was obtained by strictly objective criteria and without recourse to "eyeball" manipulation. Moreover, the overall similarities, as reflected in the percent identities, are more in line with the true distances separating the organisms than are those observed in the original pairwise alignments (Table 1).

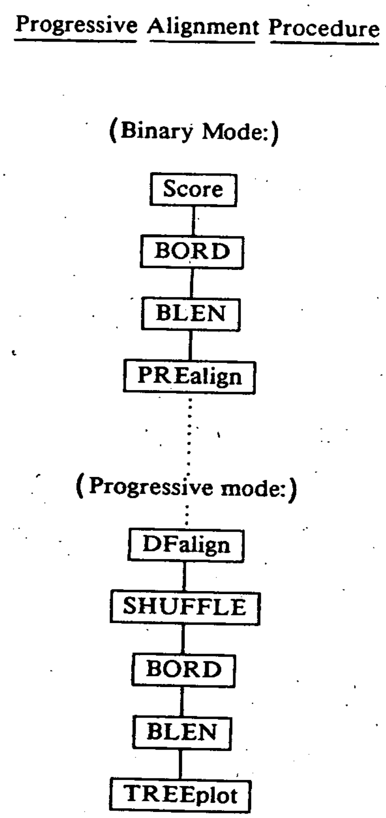

Fig. 1. Flow chart of progressive alignment procedure. Program names are shown in boxes. The program BLEN in upper portion of figure may be omitted if a tree based on pairwise alignments is not going to be constructed.

Hemoglobins

Eleven different globin sequences covering a broad spectrum of types were subjected to pairwise alignments and an initial tree constructed from the resulting difference matrix (Fig. 4a). The tree was similar to those presented in previous reports in that cyclostome globins (hagfish and lamprey) branch off in advance of the myoglobin–hemoglobin α-chain divergence (Goodman et al. 1974; Hunt et al. 1978; Feng et al. 1985). When the same 11 sequences were subjected to the progressive alignment procedure, the tree that emerged reversed the order to the more biologically reasonable situation in which the cyclostome globins are clustered with those of other vertebrates (Fig. 4b).

Also of interest are the relative positions of the plant and invertebrate hemoglobins. In the tree obtained from pairwise alignments, the plant and bacterial hemoglobins appear to be more closely related

The four-letter designations are hghu, human globin γ chain; hbhu, human globin β chain; hahu, human globin α chain; heha, hagfish hemoglobin; hbrl, lamprey hemoglobin; myhu, human myoglobin; mycr, gastropod myoglobin; hety, earthworm hemoglobin (*Tylorrhynchus*); haew, earthworm hemoglobin (*Lumbricus*); gpfb, kidney bean leghemoglobin; hbvs, bacterial hemoglobin (*Vitreoscilla*). The same designations are used in Fig. 5 and Table 2.

to the globins of higher invertebrates and vertebrates than are those from annelid worms (Fig. 4a). Again, a more traditional grouping is obtained with the progressive alignment procedure (Fig. 4b). The multiple alignment generated by the procedure (Fig. 5) appears to be an accurate depiction of the history of events during globin evolution, and the degrees of similarity of the various globins based on these alignments are also more in line with expectations than are those found from simple binary alignments (Table 2).

Tyrosine Kinase-like Sequences

We had previously aligned a set of nine tyrosine kinase-like sequences and constructed a tree based on a simple pairwise matrix (Feng et al. 1985), and it was naturally of interest to see how the progressive alignment treatment compared (Table 3). In this case, unlike the situations with the superoxide dismutases and hemoglobins, the branching orders found by the two procedures did not differ (Fig. 6a and b). The multiple sequence alignment that was generated automatically during the procedure (Fig. 7) was somewhat different from the "eyeball" alignment made previously on the basis of a series of pairwise comparisons, although the same 14 invariant residues occur coincidentally in both renditions (Fig. 7). The trees themselves are not significantly different, although the branch lengths differ slightly.

Discussion

The concept of using pairwise alignments iteratively to establish phylogenetic relationships is hardly new. Moore et al. (1973) constructed the best possible dendrogram for a set of sequences by an iterative

pairwise process, and, more recently, Hogeweg and Hesper (1984) used a heuristic approach for generating trees that also depends on successive pairwise alignments. As far as we know, however, the notion of "once a gap, always a gap," coupled with progressive pairwise alignment, has not been utilized before. Gap preservation is achieved by the insertion of neutral elements that hold the gap positions fixed during each progressive realignment.

Two things are certain: the method, while heuristic, provides multiple sequence alignments that are based on objective criteria, and trees derived from these alignments appear to be in harmony with the biology of the proteins as evidenced by the phylogeny of the organisms from which they are obtained. The simplicity of the procedure is attested to by the small number of pairwise comparisons that must be undertaken to produce the multiple alignment (Table 4). Thus, if 10 sequences are to be aligned, only 61 comparisons have to be made. This is a smaller number of alignments than is ordinarily performed when a set of jumbles is made for a single quantitative alignment. In this regard, we have eschewed the use of jumbled comparisons in the initial alignments in favor of an empirically determined average random score.

Kinds of Sequence Alignment

Broadly speaking, there are three kinds of multiple sequence alignment: (1) structural equivalence types, (2) global optimization methods, and (3) historical alignments. The first of these, structural equivalence, is used mainly by crystallographers. The goal is to align those segments of two protein sequences that occupy equivalent three-dimensional orientations. As such, these studies are usually restricted to protein families at least one member of which has had an x-ray structure determined (Bajaj and Blundell 1984). The interest is focused on present-

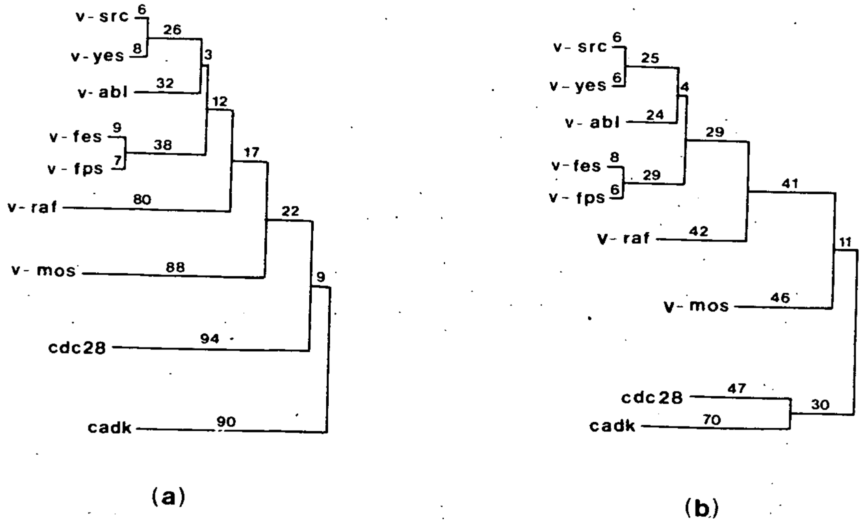

Fig. 6. Phylogenetic trees for nine tyrosine kinase-like sequences determined from a simple pairwise alignments and **b** progressive alignment. The four-letter designations are v-src, avian Rous sarcoma virus transforming factor; v-yes, avian Y73 sarcoma virus transforming factor; v-abl, Abelson murine leukemia virus transforming factor; v-fes, feline sarcoma virus transforming factor; v-fps, avian Fujinami virus transforming factor; v-raf, murine retroviral transforming factor; v-mos, mouse sarcoma virus transforming factor; cdc28, yeast cell division control factor; cadk, bovine cyclic AMP-dependent kinase. The same four-letter designations are used in Fig. 7 and Table 3.

day structure without regard for how the structures came to be.

Global optimization methods are designed to accommodate a set of sequences in a multiple alignment that maximizes overall similarity. Three-dimensional extensions of the Needleman-Wunsch algorithm, for example, have been used to achieve such alignments (Jue et al. 1980; Murata et al. 1985), and Johnson and Doolittle (1986) have used the overlapping approach pioneered by Fitch (1966, 1970) to generate four-way and five-way alignments. Again, these alignments are made without regard to historical detail.

Historical alignments are based on the notion that divergent evolution is fundamentally binary in nature. Long ago Dayhoff et al. (1972), noting that matrix methods greatly foreshorten the more ancient branches in evolutionary trees, used a common-

[a] Values are minimal numbers for simple trees; compound trees need an additional alignment for each subcluster. Also, occasional negative segments in some trees will necessitate additional alignments

ancestor approach to alignment and tree building that was historical in principle. The character-based approach that they used was much clumsier than matrix methods, however, and eventually was abandoned. Subsequently, Holmquist (1979, p 939) drew attention to the fact that parsimony methods err significantly, "the magnitude of the error increasing with the distance of the nodal sequence from the present," and, more recently, Penny and Hendy (1986) have expounded on the theme that the minimal tree cannot be the historical tree.

It is obvious that methods based on mere global optimization will consistently underestimate evolutionary distances among the least related members of the set, striving as they do to achieve maximum alignment scores. The need is to throttle the tendency for optimization while preserving the notion of similar residues replacing one another. The progressive alignment procedure presented here appears to achieve that end. In its favor, the trees generated from these alignments appear to be in accord with biological expectations.

Superoxide Dismutase Relationships

The copper–zinc superoxide dismutase sequences have been the subject of much debate since the possibility was raised that the sequence found in the prokaryote *Photobacterium leiognathi* might be the result of a horizontal gene transfer from its ponyfish host (Martin and Fridovich 1981). Although solid evidence to the contrary was provided by Steffens et al. (1983), the notion has refused to go away (Bannister and Parker 1985). Our thinking about this matter is wholly in accord with that recently expressed by Leunissen and De Jong (1986): to wit, there is no basis for supposing anything other than a conventional history of events. Indeed, either of the evolutionary trees in Fig. 2 ought to dispel thoughts of a horizontal gene transfer for this gene, the photobacter position being entirely consistent with what would be expected for a typical prokaryotic–eukaryotic divergence. On the other hand, the tree made from pairwise alignments (2a) does have an unreasonble arrangement for the fruitfly and yeast, whereas the progressive tree is quite in line with conventional phylogeny.

It should be pointed out in passing that an apparent speed-up in the rate of copper–zinc superoxide dismutase evolution has occurred among the vertebrates (Lee et al. 1985). Thus, the apparent differences between mammalian and *Drosophila* sequences are much greater than would be expected on the basis of a comparison of the *Drosophila* and yeast sequences. The fact that there appears to have been a relaxation of selection pressures on the vertebrate superoxide dismutase should not affect the branching order, of course.

Hemoglobins and Myoglobins

The progressive alignment scheme also yields reasonable results when applied to distantly related globin sequences. In contrast to phylogenies employing a maximum parsimony method (Goodman et al. 1974), the progressive method roots the lamprey

and hagfish globins to the same branch as other vertebrate hemoglobins. Interestingly, an early study employing the common ancestor approach (Dayhoff and Eck 1968) also had the lamprey in this position. With regard to the relationship of animal and plant globins, the depth of the differences warrants a good deal of caution. Nonetheless, the recently published bacterial globin sequence (Wakabayashi et al. 1986) resembles the plant globins more than it does the animal globins, and it is not impossible that an unusual genetic event involving plants and symbiotic bacteria has occurred. A larger study encompassing all the known invertebrate and plant globin sequences may reveal more about the evolutionary connections of these proteins.

Concluding Remark

It is not our intention to reopen past skirmishing about the relative merits of strict parsimony methods and alternative treatments (Fitch 1981; Holmquist and Jukes 1981). Nor is it our aim merely to add one more comment to the enormous literature on the construction of evolutionary trees with sequence data (Tateno et al. 1982; Hogeweg and Hesper 1984; Penny and Hendy 1986, to name but a few). Rather, we simply offer a heuristic procedure for a computer-determined multiple alignment of related amino acid sequences that can be effected rapidly by objective criteria. Evolutionary trees drawn directly from these alignments appear to be very much in accord with biological expectations.

Acknowledgments. We acknowledge many helpful discussions with Mark Johnson and Marcella McClure; we are especially grateful to Mark Johnson for writing the programs BORD and TREEplot. This work was supported by NIH Grant GM-34434 and a grant from the American Cancer Society.

Note Added in Proof. During the period since the acceptance of this article we have applied the procedure in numerous settings, and, in some cases, the final alignment was slightly imperfect. The situation was remedied, however, by aligning each new sequence, or set of sequences, with an average sequence of all the sequences already aligned. This was accomplished by simply looking up the matrix value for every pair of residues at each position and averaging them. We are grateful to Steve Hanks for bringing the problem to our attention and to Mark Johnson for helping with the solution.

A comprehensive set of sequence analysis programs for the VAX

John Devereux, Paul Haeberli* and Oliver Smithies

Laboratory of Genetics, University of Wisconsin, Madison, WI 53706, USA

Received 18 August 1983

ABSTRACT

The University of Wisconsin Genetics Computer Group (UWGCG) has been organized to develop computational tools for the analysis and publication of biological sequence data. A group of programs that will interact with each other has been developed for the Digital Equipment Corporation VAX computer using the VMS operating system. The programs available and the conditions for transfer are described.

INTRODUCTION

The rapid advances in the field of molecular genetics and DNA sequencing have made it imperative for many laboratories to use computers to analyze and manage sequence data. UWGCG was founded when it became clear to several faculty members at the University of Wisconsin that the there was no set of sequence analysis programs that could be used together as a coherent system and be modified easily in response to new ideas.

With intramural support a computer group was organized to build a strong foundation of software upon which future programs in molecular genetics could be based. This initial project has been completed and the resulting programs, written in Fortran 77, are available for VAX computers using the VMS operating system. Most of the programs can be used with only a terminal, although several require a Hewlett Packard plotter.

UWGCG software has been installed for testing at eight different institutions. A simple method has been developed for transferring and maintaining this system on other VAX computers.

DESIGN PRINCIPLES

UWGCG program design is based on the "software tools" approach of Kernighan and Plauger(1). Each program performs a simple function and is easy to use. The programs can be used independently in different combinations so

that complex problems are solved by the use of several programs in succession. New programming is simplified since less effort is required to bridge a gap between existing programs.

UWGCG software is designed to be maintained and modified at sites other than the University of Wisconsin. The program manual is extensive and the source codes are organized to make modification convenient. Scientists using UWGCG software are encouraged to use existing programs as a framework for developing new ones. Our copyright can be removed from any program modified by more than 25% of our original effort.

PROGRAMS AVAILABLE FROM UWGCG

The programs described below are named and defined individually in Table 1. Program names in the text are underlined.

Comparisons

Comparisons may be done with "dot plots" using the method of Maizel and Lenk(2). Optimal alignments can be generated by the methods of Needleman and Wunsch(3), of Sellers(4), and the "local homology" method of Smith and Waterman(5). The Smith and Waterman alignment algorithm is also the most sensitive method available for identifying similarities between weakly related sequences.

Mapping and Searching

Mapping is available in several formats. Graphic maps display all of the cuts for each restriction enzyme on parallel lines. This graphic map facilitates selection of enzymes for isolating any region of a sequenced DNA molecule. Sorted maps in tabular format arrange the fragments from any digestion in order of molecular weight to show which fragments are similar in size and thus likely to be confused in gels. Another frequently used mapping format, designed by Frederick Blattner(6), displays the enzyme cuts above the original DNA sequence. Both strands of the DNA and all six frames of translation are shown.

All mapping programs will search for user-specified sequences, allowing features to be marked at the appropriate position on a restriction map. The mapping and searching programs can be used to aid site-specific mutagenesis experiments by showing where mutations could generate new restriction sites. All of the positions in a sequence where a synthetic probe could pair with one or more mismatches can also be located. Sequences related to less precisely defined features such as promoters or intervening sequence splice sites, can be located with a program that uses a consensus sequence as a probe. The

Table 1

Programs Available from UWGCG

Name	Function
DotPlot+	makes a dot plot by method of Maizel and Lenk(2)
Gap	finds optimal alignment by method of Needleman and Wunsch(3)
BestFit	finds optimal alignment by method of Smith and Waterman(5)
MapPlot+	shows restriction map for each enzyme graphically
MapSort	tabulates maps sorted by fragment position and size
Map	displays restriction sites and protein translations above and below the original sequence(Blattner,6)
Consensus	creates a consensus table from pre-aligned sequences
FitConsensus	finds sequences similar to a consensus sequence using a consensus table as a probe
Find	finds sites specified interactively
Stemloop	finds all possible stems (inverted repeats) and loops
Fold*	finds an RNA secondary structure of minimum free energy by the method of Zuker(7)
CodonPreference+	plots the similarity between the codon choices in each reading frame and a codon frequency table(8)
CodonFrequency	tabulates codon frequencies
Correspond	finds similar patterns of codon choice by comparing codon frequency tables (Grantham et al,9)
TestCode+	finds possible coding regions by plotting the "TestCode" statistic of Fickett(10)
Frame+	plots rare codons and open reading frames(8)
PlotStatistics+	plots asymmetries of composition for one strand
Composition	measures composition, di and trinucleotide frequencies
Repeat	finds repeats (direct, not inverted)
Fingerprint	shows the labelled fragments expected for an RNA fingerprint
Seqed	screen oriented sequence editor for entering, editing and checking sequences
Assemble	joins sequences together
Shuffle	randomizes a sequence maintaining composition
Reverse	reverses and/or complements a sequence
Reformat	converts a sequence file from one format to another
Translate	translates a nucleotide into a peptide sequence
BackTranslate	translates a peptide into a nucleotide sequence
Spew	sends a sequence to another computer
GetSeq	accepts a sequence from another computer
Crypt	encrypts a file for access only by password
Simplify	substitutes one of six chemically similar amino acid families for each residue in a peptide sequence
Publish	arranges sequences for publication
Poster+	plots text (for labelling figures and posters)
OverPrint	prints darkened text for figures with a daisy wheel printer

+ requires a Hewlett Packard Series 7221 terminal plotter
* Fold is distributed by Dr. Michael Zuker not UWGCG.

mapping programs can also be used on protein sequences to identify the peptides resulting from proteolytic cleavage.

Secondary Structure

Three programs are available to examine secondary structure in nucleic acids. The program StemLoop identifies all inverted repeats. An implementation of Dr. Michael Zuker's Fold program(7) finds an RNA secondary structure of minimum free energy based on published values of stacking and loop destabilizing energies. The "dot plot" comparison (mentioned above) of a sequence compared to its opposite strand gives a graphic picture of the pattern of inverted repeats in a sequence.

Analysis of Composition and the Location of Genetic Domains

Regions of a sequence with non-random base distribution can be displayed with three graphic tools designed to identify genetic domains. The program CodonPreference(8) identifies potential coding regions by searching through each reading frame for a pattern of preferred codon choices. The CodonPreference plot predicts the level of translational expression of mRNAs and helps identify frame shifts in DNA sequence data. Patterns of codon choice can be compared with the program Correspond(9). When a strong pattern of codon preferences is not expected, the "TestCode" statistic of Fickett(10) can be plotted to show regions of compositional constraint at every third base. Another program plots asymmetries of composition by strand. Strand asymmetries have been associated with genetic domains by several authors(11)(12). A fourth program called Frame marks the positions of rare codons and open reading frames on a graph showing all six reading frames.

Several tools are available to measure content and to count dinucleotide, trinucleotide, neighbor and repeat frequencies. A program that predicts RNA fingerprint patterns and another that tabulates codon frequencies complete the group of programs that analyze composition.

Sequence Manipulation

Sequences may be entered, assembled, edited, reversed, randomized, reformatted, translated, back-translated, documented, transferred, or encrypted rapidly with a large set of sequence manipulation tools.

A screen-oriented editor is available that allows sequences to be entered and checked. After a sequence is entered, it may be reentered for proofreading. Whenever a reentered base is at variance with the original, the terminal bell rings and the position is marked. Existing sequences can be edited quickly by moving directly to a sequence position specified by either a coordinate or a sequence pattern. The program can reassign the terminal's

keys to place G, A, T and C conveniently under the fingers of one hand in the same order as the lanes of a sequencing gel.

Programs are available for changing sequence file format. Sequence data from any source can be used in UWGCG programs, and sequence files maintained with UWGCG software can be converted for use in other non-UWGCG programs. For instance, the programs of Roger Staden(13) or Intelligenetics Inc.(14) could be used to assemble a sequence from the sequences of many small sub-fragments generated by DNAase I digestion. The assembled sequence could then be reformatted for use in any UWGCG program. A program is available that transfers sequences to and from other computers.

Sequence Publication

A program, Publish, will format sequences into figures. Publish has alternatives for line size, numbering, scaling, translation and comparison to other sequences. Poster is a program that will plot text on figures.

GENERAL FEATURES OF UWGCG SOFTWARE

Interactive Style

Each program is run by simply typing its name. Every parameter required by the program is obtained interactively. Questions are answered with a file name, a yes, a no, a number, or a letter from a menu. Default answers are displayed. Programs are insensitive to absurd answers and will ask the question again if, for instance, you name a file that does not exist or if you use a nonnumeric character when typing a number. Special features such as plotting features oriented to publication, are obtained by using an extra word next to the program's name when the program is run. Thus parameter queries are kept to a minimum for the normal use of each program.

Data

Both the NIH-GenBank(15) and the EMBL(16) nucleotide sequence data libraries are available "on-line" to any UWGCG program. A Search utility will locate sequences in the libraries by key word. A Find utility will locate library entries containing any specified sequence. A program is available that installs the new data sent periodically from GenBank and EMBL to update their data libraries.

All of the data in the system are stored in text files that can be read and modified easily. Every data file has an English heading describing the contents. The data files may be copied by each user for analysis or modification. Programs recognize and read user-modified input data automatically. Data files can be modified with any text editor.

Sequence File Structure

Sequences are maintained in files that allow documentation and numbering both above and within the sequence. This file format is compatible with both of the nucleic acid sequence libraries and has been adopted as the standard sequence file format by the data base project at the European Molecular Biology Lab. Because genetic manipulations commonly involve linking several molecules of known sequence, UWGCG sequence files are designed to support concatenation by allowing comments to appear within the sequences at any location. Coding sequences or the boundaries between cloning vector and insert, for instance, can be marked within the sequence itself for immediate identification.

Sequence Symbols

All possible nucleotide ambiguities and all standard one-letter amino acid codes are part of the UWGCG symbol set that includes all alphabetic characters plus five additional characters. The proposed IUB-IUPAC standard nucleotide ambiguity symbols(17) are used for the mapping, searching and comparison programs. Lower case characters are used in sequences to indicate uncertainty as distinct from ambiguity. This allows the entire lexicon of symbols to be reused with same meaning, but with the prefix "maybe-." This reuse of the symbol set in lower case makes the uncertainty symbols more complete, understandable and visible.

Symbol Comparison

Sequence analysis programs generally make comparisons between sequence symbols (bases or amino acids) in order to find enzyme sites, create alignments, locate inverted repeats etc. These symbol comparisons are handled in several ways.

Symbol comparisons for alignment, comparison and secondary structure analysis are made by looking up a value in a symbol comparison table for the quality of the match. The table might contain 1's for matches and 0's for mismatches. If amino acids are being compared, however, a real number could be assigned at each position based on some previously assigned chemical similarity of the pair of residues or on the mutational distance between their codons. Standard symbol tables are provided by UWGCG, but the system is designed to allow each user to specify his own values.

Symbols comparisons for mapping and searching operations in nucleic acids are made by converting the IUB-IUPAC symbols into a binary code. The bits of this code represent G, A, T and C with ambiguity symbols causing more than one

bit to be set. A group of library functions identify overlap between the bits for each IUB-IUPAC symbol.

Documentation

Documentation is available both in printed form and on the terminal screen. A 350 page manual describes the operation of each program in detail, gives practical considerations and shows what will appear on the screen during a session with the program. Output files and plots are shown for the session. The data for the session shown in the documentation are included with the system so that the each program's operation can be checked. The "on-line" documentation is the same as the manual, but can be changed immediately when a program is modified.

All programs write output to files that are completely documented and sensibly organized for input to other programs. The input data, the program and the parameters used are clearly identified in every output file.

Procedure Library

UWGCG programs are written largely as calls to a library of 250 procedures designed to manipulate biological sequences. These procedures use data and file structures which have been designed to simplify program modification. For instance, standard operations such as reading sequences from files are always handled by a single library procedure. Thus a change in sequence file format requires only one subroutine to be modified for the new format to be acceptable to all of the programs in the system. Command procedures are available to help modify the library. The procedure library can be used by programs written in any language.

DISTRIBUTION OF UWGCG SOFTWARE

Intent

The intent of UWGCG is to make its software available at the lowest possible cost to as many scientists as possible.

Fees

A fee of $2,000 for non-profit institutions or $4,000 for industries is being charged for a tape and documentation for each computer on which UWGCG software is installed. While no continuing fee is required, UWGCG software, like the field it supports, is changing very rapidly. A consortium of industries and academic laboratories is planned to support the project in the future. The consortium will entitle its members to periodic updates and to influence the direction of new programming undertaken by UWGCG in return for a pledge of continuing financial support.

Copyrights

UWGCG retains the copyrights to all of its software and UWGCG must be contacted before all or any part of the its software package is copied or transferred to any machine. UWGCG is, however, mandated to provide research tools to help scientists working in the area of molecular genetics and we are glad to see our source codes become the basis of further programming efforts by other scientists. Copyright can be removed for any program modified by more than 25% of its original effort.

Tape Format

The UWGCG package is usually distributed in VAX/VMS "backup" format on a 9 track magnetic tape recorded at 1600 bits/inch. The system consists of about 1000 files using about 20,000 blocks at 512 bytes/block. The current versions of the GenBank and EMBL nucleotide sequence data bases are normally included which add another 3,000 files and require another 20,000 blocks.

Upon request UWGCG will make a card image tape of all of the Fortran 77 programs and procedures for reading on computers other than the VAX. The card image tape is usually provided at 1600 bits/inch with 80 characters/record and 10 records/block. Adaptation of UWGCG software to systems other than VAX/VMS may take considerable effort.

Equipment Required

UWGCG programs and command procedures will run on a Digital Equipment Corporation (DEC) VAX computer that is using version 3.0 or greater of the DEC VMS operating system. A tape drive is necessary; a floating point accelerator and a DEC Fortran compiler are helpful, but not required. All programs can be run from a DEC VT52 or VT100 terminal. Seven programs, as noted in table 1, require a Hewlett Packard 7221 terminal plotter wired in series with the terminal. Several utilities support a daisy wheel compatible printer attached to the terminal's pass-through port, however, all programs write output files suitable for printing on any standard device.

Inquiries

Inquiries may be sent to John Devereux at the Laboratory of Genetics, University of Wisconsin, Madison, WI, USA 53706, (608) 263-8970. UWGCG is not licensed to distribute Fold(7), but the UWGCG implementation is available from Michael Zuker, Division of Biological Sciences, National Research Council of Canada, 100 Sussex Drive, Ottawa, Canada, K1A OR6 (613) 992-4182.

ACKNOWLEDGEMENTS

UWGCG was started with software written for Oliver Smithies' laboratory

with NIH support from grants GM 20069 and AM 20120. UWGCG is directed by John Devereux and is operated as a part of the Laboratory of Genetics with the advice of a steering committee consisting of Richard Burgess, James Dahlberg, Walter Fitch, Oliver Smithies and Millard Susman. UWGCG is currently supported with intramural funds and with fees paid by the faculty and industries using the facility in Madison. This article is paper number 2684 from the Laboratory of Genetics, University of Wisconsin.

A comparison of eukaryotic viral 5′-leader sequences as enhancers of mRNA expression *in vivo*

Daniel R.Gallie, David E.Sleat, John W.Watts[1], Philip C.Turner[2] and T.Michael A.Wilson*

Departments of Virus Research and [1]Cell Biology, John Innes Institute, AFRC Institute of Plant Science Research, Colney Lane, Norwich NR4 7UH and [2]Department of Biochemistry, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK

Received August 5, 1987; Accepted September 25, 1987

ABSTRACT

The 5'-untranslated leader sequences of several plant RNA viruses, and a portion of the 5′-leader of an animal retrovirus, were tested for their ability to enhance expression of contiguous open reading frames for chloramphenicol acetyltransferase (CAT) or β-glucuronidase (GUS) in tobacco mesophyll protoplasts, Escherichia coli and oocytes of Xenopus laevis. Translation of capped or uncapped transcripts was substantially enhanced in almost all systems by the leader sequence of either the U1 or SPS strain of TMV. All leader sequences, except that of TYMV, stimulated expression of 5′-capped GUS mRNA with the native prokaryotic initiation codon context, in electroporated protoplasts. Only the TMV leaders enhanced translation of uncapped GUS mRNAs in protoplasts and increased expression of uncapped CAT mRNA in microinjected X. laevis oocytes. In oocytes, the TYMV leader sequence was inhibitory.

In transformed E. coli, the TMV-U1 leader enhanced expression of both the native and eukaryotic context forms of GUS mRNA about 7.5-fold, despite the absence of a Shine-Dalgarno region in any of the transcripts. The absolute levels of GUS activity were all about 6-fold higher with mRNAs containing the native initiation codon context. In E. coli, the leaders of AlMV RNA4 and TYMV were moderately stimulatory whereas those of BMV RNA3, RSV and the SPS strain of TMV enhanced GUS expression by only 2- to 3-fold.

INTRODUCTION

Cis-acting features which influence the selection and translation of eukaryotic mRNAs are poorly understood. Surveys of sequences upstream from the AUG start codon have failed to identify a universal consensus sequence which might act as the eukaryotic equivalent of the prokaryotic Shine-Dalgarno region, a region essential for the expression of prokaryotic mRNAs in E. coli (1). Secondary structures within the 5′-untranslated leaders of some eukaryotic mRNAs have been claimed to promote

(2,3) or inhibit (4) translation initiation. In prokaryotic mRNAs, selection of start codons may also be influenced, in part, by low surrounding secondary structure (5). In the relaxed scanning model (6), 40S ribosomal subunits bind at the 5′-end of an mRNA and scan until the first AUG in the optimal context (5′-ACCAUGG-3′) is reached, at which point translation begins. Beyond this, little is known about the longer-range effects of specific sequences on expression of eukaryotic mRNA.

We have shown that translation of prokaryotic (7) and eukaryotic (8) mRNAs is greatly enhanced by a contiguous derivative of the 68-nucleotide, 5′-leader sequence of tobacco mosaic virus (TMV), U1 strain (called Omega (Ω); 9,10). The stimulatory effect of this Ω-like sequence (referred to as Ω′-U1) has been observed in vitro and in vivo, in both eukaryotic and prokaryotic translation systems. Tyc and co-workers (11) identified a second 80S ribosome binding site, centred on residues 14-16 (AUU) within Ω-U1 (or Ω′), which was upstream of, and in frame with, the predicted ribosome binding site at the first AUG codon (residues 68-70 in Ω-U1). The latter initiates synthesis of the 126,000 dalton (126Kd) protein encoded by TMV RNA. In Ω-U1 (and Ω′-U1), 51 nucleotides separate the AUU and AUG sequences which, in the presence of an inhibitor of elongation (sparsomycin), permit two ribosomes to bind simultaneously without steric hindrance. Initiation of translation of genomic TMV RNA under these conditions has been claimed to result in two unique dipeptides, Met-Thr and Met-Ala, (12) which may arise by illegitimate or legitimate initiation at the AUU and AUG sites, respectively. Yokoe and coworkers (13) demonstrated RNA-RNA hybridization between the 5′-region of Ω-U1, containing the AUU sequence, and the 3′-terminus of wheat germ 18S rRNA, again supporting the possibility of disome formation. In addition to TMV, several other viral RNA leader sequences have been shown to form disome (or even trisome) structures (2, 14-16). The 36-nucleotide leader of AlMV RNA4 binds only one ribosome (17), nevertheless it will stimulate expression of contiguous foreign gene transcripts in vitro (18).

We wished to determine whether translational enhancement was a general feature of 5′-untranslated viral leader sequences and

if the ability of a viral leader to form disomes could be correlated with its ability to enhance translation of a contiguous open reading frame. For this purpose, synthetic oligonucleotide sequences derived from the 5′-leaders of TMV (U1 strain; disome), TMV (SPS strain; disome), turnip yellow mosaic virus (TYMV; disome), alfalfa mosaic virus (AlMV) RNA 4 (monosome), brome mosaic virus (BMV) RNA 3 (disome), and the animal retrovirus, Rous sarcoma virus (RSV; disome) were analyzed for their relative abilities to stimulate expression of convenient reporter gene transcripts *in vivo*.

MATERIALS AND METHODS

Bacterial strains, plasmids, enzymes, and media

Escherichia coli strains HB101 and JM101 were obtained from F. Bolivar and J. Messing, respectively. The pSP64 derivatives pJII1, pJII101, pJII2, pJII102 have been described (7). The chloramphenicol acetyltransferase (CAT) reporter gene from Tn9 was obtained from T.J. Close (CSIRO, Canberra, Australia). The β-glucuronidase gene (GUS) and its derivatives were obtained from R. Jefferson and M. Bevan (Plant Breeding Institute, Maris Lane, Trumpington, Cambridge). SP6 RNA-polymerase, human placental RNase inhibitor, DNA polymerase I (Klenow fragment), T4 DNA ligase and all restriction endonucleases were purchased from Boehringer (Mannheim), Pharmacia Ltd., or New England BioLabs. Purified CAT was bought from Pharmacia Ltd. SOC medium (19) was used to prepare competent *E. coli* cells, and L-broth (20) was used for all other cultures.

Plasmid DNA purification and manipulation

Preparative scale (21) and small scale (22) DNA isolations were as described. Standard DNA manipulations were performed essentially as described (21).

Oligodeoxyribonucleotide synthesis

Oligodeoxyribonucleotides were synthesized by S. Gilmore and A.J. Northrop (Institute of Animal Physiology, Babraham, Cambridge) using a Biosearch 8600 4-channel DNA synthesizer and the β-cyanoethyl-phosphoramidite method (23). For each full-length dsDNA viral leader, one complete strand (the coding strand) was synthesized with a 5′-*Hin*dIII site (+1 base) and a

3′- *SalI* site (+ 1 base), for subsequent insertion into the transcription plasmid pJII1. A second complementary oligodeoxyribonucleotide (24-mer) was then annealed, and the dsDNA filled-in by polymerization with either DNA polymerase I (Klenow fragment) or reverse transcriptase.

Construction of trp promoter plasmid pJII168 for E. coli transformation

A 90 base pair (bp) *HindIII/BamHI* fragment containing the tryptophan (*trp*) promoter (P-L Biochemicals, Inc.) was introduced into the *HindIII/BamHI* sites of pJII1 (7), from which a 400bp *BamHI* fragment containing the TMV origin-of-assembly sequence had been removed. The *HindIII* site upstream from the *trp* promoter was removed by digestion with *HindIII*, filling-in with DNA polymerase I (Klenow fragment), followed by re-ligation. A *HindIII* site was then introduced at the 3'-end of the promoter by replacing the 25bp *HpaI/SalI* fragment with a synthetic 17bp *HpaI/SalI* fragment, containing a *HindIII* site positioned at the transcription start site.

RNA synthesis

In vitro transcription of linearized plasmid DNAs was carried out using bacteriophage SP6 RNA polymerase (24). Capped transcripts were obtained by modifying the published reaction conditions to include 200µ*M* GTP and 1.5m*M* $G^{5'}ppp^{5}G$ (Pharmacia, Ltd). RNAs were quantitated either by trace-labelling with α-[^{32}P]-rUTP or by formaldehyde-agarose gel electrophoresis as described (24).

Preparation and electroporation of tobacco mesophyll protoplasts

Mesophyll protoplasts were isolated from leaves of *Nicotiana tabacum* (cv. Xanthi) and stored in 0.7*M* mannitol (25). Electroporation of RNA into protoplasts and incubations were carried out as previously described (7).

After incubation, electroporated protoplasts were sedimented, resuspended and broken by ten passages through a 26-gauge needle in 400µl of 0.25*M* Tris-HCl, pH 7.4, containing 10m*M* dithiothreitol (DTT). Extracts were microcentrifuged at 10,000x*g* for 10 min at 4°C.

Microinjection of Xenopus laevis oocytes

X. laevis were purchased from Xenopus Ltd., South Nuffield,

U.K. Two ng of each synthetic uncapped SP6 mRNA were injected into the cytoplasm of stage 6 oocytes in batches of 25 using standard procedures (26). Oocytes were incubated for 21 hours in Modified Barth's Saline, then washed briefly in distilled water. Extracts from *Xenopus* oocytes were prepared by resuspending each sample in 0.25*M* Tris-HCl, pH 7.4, 10m*M* DTT (20µl/oocyte), followed by sonication for 10 sec. Insoluble material was removed by microcentrifugation for 15 min and fractions of the supernatant representing equivalent numbers of oocytes were assayed for CAT activity.

CAT assay

The protein concentration of each supernatant from *X. laevis* oocytes or tobacco protoplasts was determined by the method of Bradford (27). The CAT assay was essentially as described (28), but used 0.25*M* Tris-HCl, pH 7.4, containing 10m*M* DTT and 30m*M* acetyl-CoA. Quantitation of the thin-layer chromatograph was achieved by cutting out the area corresponding to each ^{14}C-labelled spot and counting in a toluene-based scintillant containing 4% (w/v) PPO and 0.005% (w/v) POPOP.

GUS assay

GUS activity was measured spectrophotometrically or fluorimetrically in 0.5ml assay buffer containing 50m*M* sodium phosphate, pH 7.0, 10m*M* 2-mercaptoethanol, 0.1% (v/v) Triton X-100 and either 1m*M* *p*-nitrophenyl-β-D-glucuronide (PNPG; for *E. coli* extracts) or 0.5m*M* 4-methyl-umbelliferyl-β-D-glucuronide (MUG; for tobacco protoplast extracts). Assays were carried out at 37°C and were terminated by addition of 0.4ml 2.5*M* 2-amino-2-methyl-1,3-propanediol for *E. coli* extracts, or 0.5ml 0.2*M* Na_2CO_3 for protoplast extracts. *p*-Nitrophenol absorbance was measured at 415nm using a Pye Unicam SP1800 Spectrophotometer. Fluorescence was measured by excitation at 365nm and emission at 455nm in a Perkin-Elmer 204 Fluorescence Spectrophotometer.

In situ localization of GUS activity in SDS-polyacrylamide gels

Samples of protoplast extracts containing equivalent amounts of protein were incubated with an equal volume of gel loading buffer (29) at room temperature for 15 min, followed by SDS-polyacrylamide gel electrophoresis (29) in a 12.5% (w/v) gel at 50V for 16 hours. The gel was rinsed 4 times in 100ml assay

buffer (without the glucuronide substrate) for a total of 2 hours, incubated on ice in assay buffer containing 0.5mM MUG for 30 min, and transferred to a glass plate at 37°C for 30 min. The gel was then sprayed with 0.2M Na_2CO_3 and photographed under long-wavelength ultraviolet light using a Wratten 2E filter.

RESULTS

Quantitation of the effect of Ω'-U1 and initiation codon context on expression of GUS mRNAs in tobacco protoplasts.

A derivative of the TMV leader, Ω'-U1 (Fig. 1), has been shown to enhance translation of CAT mRNA in tobacco mesophyll protoplasts, and other eukaryotic and prokarotic systems (7). To quantitate the effect of Ω'-U1 in protoplasts more precisely, we used the GUS reporter gene (30). A SalI-ended fragment containing the GUS gene from pRAJ235 (30) was introduced into the SalI site of the pSP64-derived vectors pJII101 and pJII1 (7), resulting in pJII120 and pJII119, with or without a 5′-proximal Ω'-U1 sequence, respectively. The native SalI GUS fragment had 19 nucleotides upstream of the AUG start codon (Fig. 1). The context of this AUG codon (5′-CCCUUAUGU-3′) was, according to Kozak (6), inefficient for eukaryotic translation (hereafter referred to as "bad context" GUS). To determine whether the effect of Ω'-U1 on mRNA expression was influenced by the context of the initiation codon, a SalI fragment of a derivative of the GUS gene with an initiation codon context (5′-CGACCAUGG-3′) close to the consensus sequence for optimal eukaryotic translation initiation was constructed (in pRAJ275; (8)). This derivative (hereafter referred to as "good context" GUS) had only 7 nucleotides upstream of the AUG (Fig. 1). This SalI fragment was introduced into pJII101 and pJII1 as for "bad context" GUS, resulting in pJII140 and pJII139, with or without a 5′-proximal Ω'-U1 sequence, respectively. 5′-Capped or uncapped mRNAs were synthesized *in vitro* by SP6 RNA polymerase on BglII-linearized pJII119, pJII120, pJII139, pJII140 templates. Eight micrograms of each transcript were electroporated into tobacco mesophyll protoplasts and incubated for 20 hours at 25°C. Assaying protoplast extracts by GUS-activity gel (Fig. 2) revealed that "good context" GUS mRNAs (tracks 6-9) were expressed more efficiently

GUCGACCAUGG — GUS Leader "Good" Context

Fig. 1. DNA constructs representing the 5′-untranslated viral leaders tested for translational enhancement. The sequence of the untranslated portion of each viral RNA up to position +4 (6) of the first open reading frame is shown. Each initiation codon (AUG) is underlined. The region of each leader sequence used in the construction of the corresponding oligodeoxyribonucleotide is marked above the RNA sequence by the bold line (the uppermost being Ω′-U1). Terminal restriction sites for HindIII and SalI were present in each DNA construct. Additional nucleotides present between the SalI site and the start codon (underlined) of the CAT or GUS reporter gene cassettes are shown below as RNA sequences.

than "bad context" GUS mRNAs (tracks 2-5). In addition, the presence of Ω′-U1 on both the "good" and "bad context" GUS mRNAs enhanced expression considerably, whether the mRNAs were capped or not. Accurate fluorimetric quantitation of the kinetics of GUS activity (Fig. 3) and hence of GUS mRNA expression (Table 1), revealed that the levels of expression of uncapped "good" or "bad context" GUS mRNAs were below the limit of detection and only became detectable when the transcripts were capped and/or when Ω′-U1 was present. In all cases, the presence of Ω′-U1

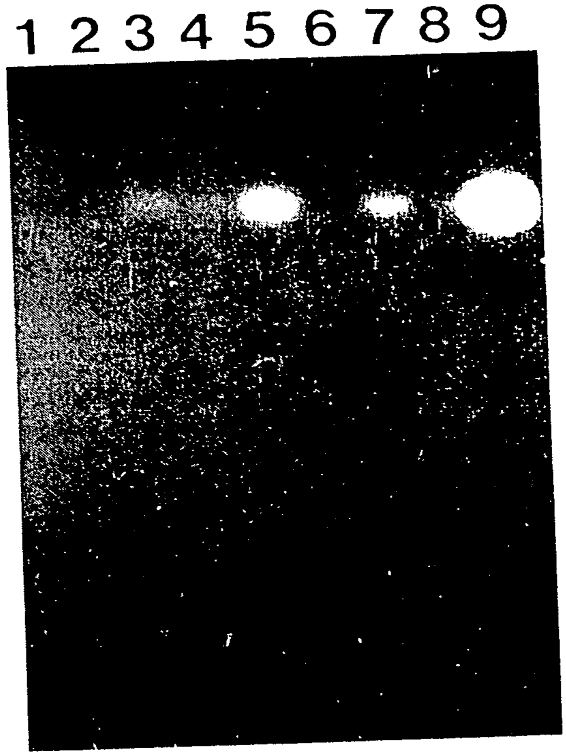

Fig. 2. β-glucuronidase activity-gel of extracts from electroporated tobacco mesophyll protoplasts. Extract volumes representing equivalent amounts of protein were loaded onto each track. Both "bad" and "good context" GUS mRNAs were used to quantitate the effect of Ω'-U1 or a 5′-cap on expression of the enzyme. Electroporated RNAs were: track 1, no RNA (mock); tracks 2-5, "bad context" mRNAs and tracks 6-9, "good context" mRNAs. Tracks 2 and 6, GUS mRNA; tracks 3 and 7, Ω'-U1-GUS mRNA; tracks 4 and 8, 5′-capped-GUS mRNA; tracks 5 and 9, 5′-capped-Ω'-U1-GUS mRNA.

enhanced expression markedly, stimulating the "bad context" GUS mRNA approximately 20-fold. Stimulation of "good context" GUS mRNA by Ω'-U1 was even greater, showing an 80-fold increase with the capped form of the transcript (Table 1).

<u>Other viral leader sequences as translational enhancers in tobacco protoplasts.</u>

To determine whether the phenomenon of translational enhancement is associated with all viral RNA leader sequences or only with those leaders which form disome structures, <u>Hin</u>dIII and <u>Sal</u>I-linkered oligonucleotides were synthesized which incorporated the 5′-leader sequences of: TMV (SPS strain), TYMV, AlMV RNA4, BMV RNA3, and part of RSV RNA (Fig.1). Due to constraints of synthesis only the 5′-112 residues of the 380-nucleotide RSV

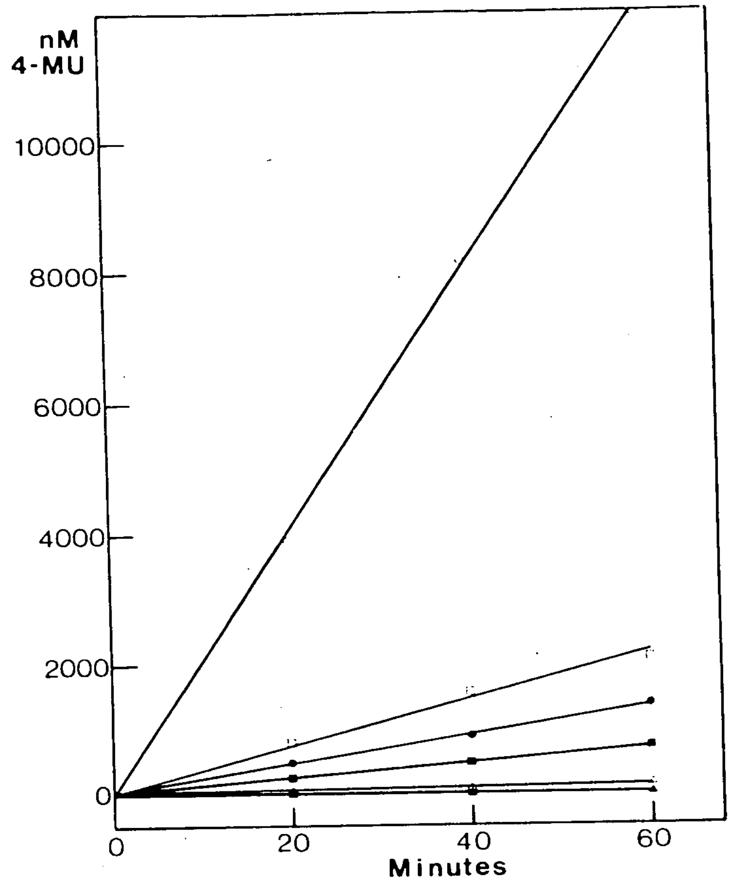

Fig. 3. Kinetic analysis of β-glucuronidase activity in extracts from electroporated tobacco mesophyll protoplasts. leader (3) were synthesized. This includes the region (residues 9-53) of the native RSV leader shown to act as the binding site for a second 80S ribosome (16). For cloning purposes, these oligonucleotides were manipulated in an identical fashion to Ω'-U1 (7). A family of SP6-transcripts in which each leader was located upstream of the "bad context" GUS gene were electroporated into tobacco protoplasts. Only the Ω'-U1 and, to a lesser extent, the Ω'-SPS leaders proved stimulatory for uncapped transcripts (Table 2). However, when the transcripts were capped, stimulation was observed with the leaders of AlMV RNA4, BMV RNA3

TABLE 1

Translational enhancement by Ω'-U1 on GUS mRNAs electroporated into tobacco protoplasts

SP6-RNAs	Initiation codon context	Specific activity (nmoles MUG hydrolysed/ min/µg protein)	Fold-stimulation
Uncapped			
GUS	bad	<0.01	1
Ω'-U1-GUS	bad	0.18	>18
GUS	good	<0.01	1
Ω'-U1-GUS	good	0.35	>35
5′-Capped			
GUS	bad	0.03	1

GUS	good	0.04	1
Ω'-U1-GUS	good	3.2	80

and "RSV" as well as Ω'-U1 and Ω'-SPS. Only with the TYMV leader did the level of GUS activity remain below the limit of detection.

Other viral leader sequences as translational enhancers in X. laevis oocytes

We have shown (7) that *Xenopus* oocytes, microinjected with capped or uncapped CAT mRNAs, gave approximately 3- to 4-fold more CAT activity when the Ω'-U1 leader sequence was present. In common with most (or all) animal cells, *Xenopus* oocytes contain high levels of endogenous GUS activity. It was therefore not feasible to assay the different viral leader sequences using GUS mRNA as the reporter. Consequently, various pSP64-based leader constructs, each containing the CAT gene, were transcribed and the uncapped mRNAs microinjected into oocytes. In this experiment, the presence of Ω'-U1 gave a 7.5-fold enhancement of CAT activity (Fig. 4). This probably reflects the better quality oocytes than were used previously (7). The Ω'-SPS

TABLE 2

Translational enhancement by various viral leaders on "bad context" GUS mRNAs electroporated into tobacco protoplasts

SP6-RNAs	Specific activity (nmoles MUG hydrolysed/ min/μg protein)	Fold-stimulation
Uncapped		
GUS	< 0.01	1
Ω'-U1-GUS	0.25	> 25
Ω'-SPS-GUS	0.15	> 15
TYMV-GUS	< 0.01	-
AlMV RNA4-GUS	< 0.01	-
BMV RNA3-GUS	< 0.01	-
"RSV"-GUS	< 0.01	-
5′-Capped		
GUS	0.03	1
Ω'-U1-GUS	0.54	18
Ω'-SPS-GUS	0.43	14
TYMV-GUS	< 0.01	-
AlMV RNA4-GUS	0.23	8
BMV RNA3-GUS	0.23	8
"RSV"-GUS	0.23	8

sequence gave a similar (6-fold) level of enhancement. The BMV RNA3, "RSV", and AlMV RNA4 leaders were not stimulatory in this system. The TYMV leader sequence appeared to reduce expression of CAT mRNA.

Enhancement by viral leader sequences in prokaryotic cells

In previous work (7), Ω'-U1 was shown to be stimulatory *in vitro* in an *E. coli* translation system. The reporter gene sequences used encoded CAT or neomycin phosphotransferase (NPTII). In both cases, the transcripts contained the natural prokaryotic

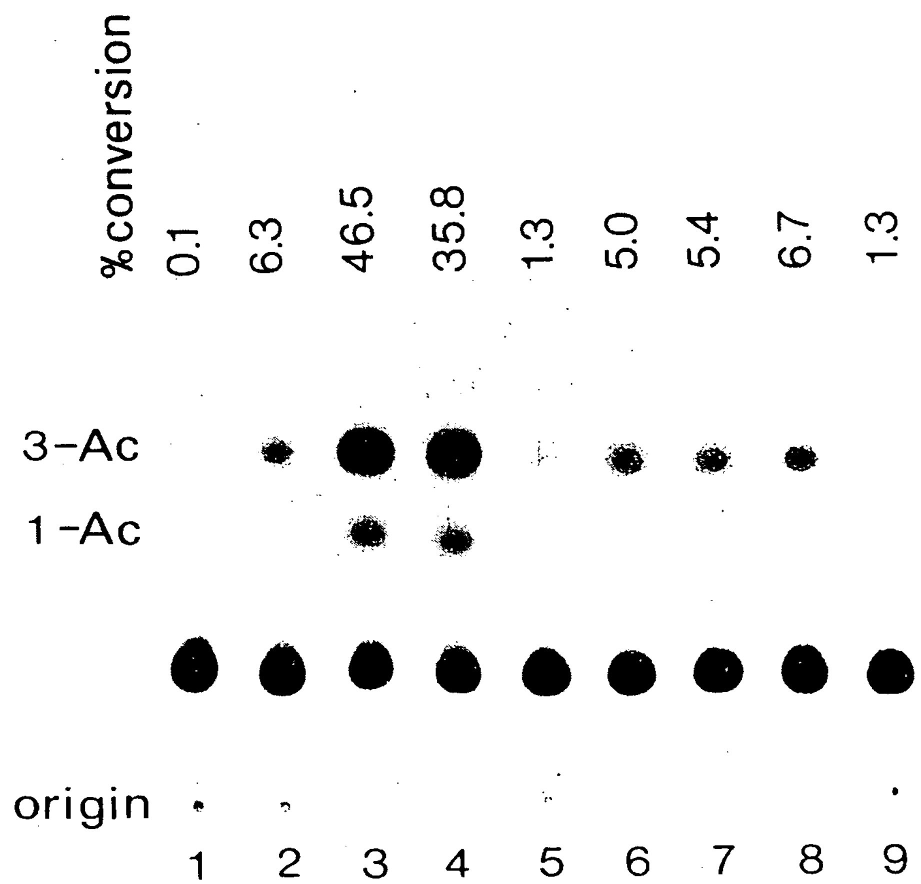

Fig. 4. The effect of various viral leader sequences on expression of CAT mRNAs microinjected into X. laevis oocytes. Oocyte extract volumes (equivalent to 0.25 x cell) were assayed in each case. Conversion (%) of ^{14}C-chloramphenicol into its mono-acetylated form, is shown above each track. Microinjected RNAs were: track 1, no RNA (mock); track 2, CAT mRNA; track 3, Ω'-U1-CAT mRNA; track 4, Ω'-SPS-CAT mRNA; track 5, TYMV-CAT mRNA; track 6, AlMV RNA4-CAT mRNA; track 7, BMV RNA3-CAT mRNA; track 8, "RSV"-CAT mRNA; track 9, 0.1 unit purified CAT enzyme added to an equivalent volume of extract as in track 1. The dried tlc plate was autoradiographed at room temperature for 4 hours before excising and counting the relevent ^{14}C-labelled spots.

Shine-Dalgarno (S-D) ribosome-binding site. The S-D sequence was located between the 3′-end of Ω'-U1 and the start of the open reading frames for CAT or NPTII. The S-D region is considered to be the most critical feature of a prokaryotic mRNA, signalling the attachment of a 30S ribosomal subunit to initiate translation at a downstream start codon. Nevertheless, with Ω'-U1 positioned upstream from the natural S-D region of CAT or NPTII, there was a significant enhancement of translation in vitro in

HindIII SalI BamHI BglII

Fig. 5. Trp-promoter construct used to assay the effect of viral leader sequences on expression of various GUS gene transcripts *in situ*, in *E. coli*. -35, -10, and operator regions of the promoter are designated above the sequence. Restriction sites are underlined below. The arrow indicates the site of transcription initiation. GUS gene cassettes were introduced at the SalI site of pJII168 after the various HindIII/ SalI leader cartridges (Fig. 1) had first been inserted.

E. coli. Recently (8), we have shown that Ω'-U1 also stimulates translation of eukaryotic mRNAs, which contain no S-D-like sequence, *in vitro* in an *E. coli* cell-free system.

To complement these observations, we examined the effect of Ω'-U1 on the *in vivo* expression of a prokaryotic mRNA which lacked a S-D region. A derivative of the tryptophan (*trp*) promoter was constructed (Fig. 5) in the plasmid pJII168. Although the HindIII site altered the native sequence of the *trp* operator region slightly, this derivative retained the regulation associated with the wild-type *trp* promoter (data not shown). The position of the HindIII site resulted in addition of only 4 nucleotides upstream of each leader construct, in contrast to the 12-additional nucleotides present in our *in vitro* SP6 transcripts. The SalI-ended "bad context" GUS gene fragment has the native (*E. coli*) context of the AUG codon and 13-nucleotides upstream from the AUG (Fig. 1). In the native GUS gene, the S-D region began just upstream of this 13-nucleotide leader, but this has now been replaced by a sequence containing the SalI site. When the "bad context" GUS gene was introduced downstream of the *trp* promoter and transformed HB101 cells were induced and assayed, a low but measurable level of GUS activity was detected (Table 3). This is in agreement with the previous observation (31) that the presence of a complete S-D sequence can be advantageous but is not essential for gene expression. Insertion of Ω'-U1 between the *trp* promoter and the GUS sequence resulted in a 7-fold increase

TABLE 3
Translational enhancement by various viral leaders on GUS mRNAs in *E. coli* transformed with a recombinant *trp* promoter plasmid

Leader-GUS construct	Initiation codon context	Specific activity (nmoles PNPG converted/ min/μg protein)	Fold-stimulation
GUS	bad	24	1
Ω'-U1-GUS	bad	162	7
GUS	good	3.8	1
Ω'-U1-GUS	good	31	8
Ω'-SPS-GUS	good	7.4	2
TYMV-GUS	good	20	5
AlMV RNA4-GUS	good	21	6
BMV RNA3-GUS	good	10	3
"RSV"-GUS	good	6.4	2

in GUS activity, a level in good agreement with that observed previously for prokaryotic transcripts which contained a S-D region (7,8). This observation contradicts the view that, in all cases, *E. coli* transcripts must have a S-D region for efficient expression. The "good context" GUS mRNA has had the initiation codon context dramatically altered from that of the native gene, and it lacks all the native GUS leader sequence - now replaced with the *Sal*I site and one C-residue (Fig. 1). The *trp* promoter construct containing this "good context" GUS resulted in extremely low, but detectable, levels of GUS activity. Even in this severely altered context, addition of the Ω'-U1 leader produced an 8-fold stimulation in expression of GUS mRNA.

As described above, some residual sequences of the natural GUS mRNA leader were present in the "bad context" GUS construct. Because these might provide some cryptic S-D function, the "good context" GUS construct was chosen as the most sensitive reporter to assay for the effect of the other viral RNA leaders on pro-

karyotic translation *in vivo*. The AlMV RNA4 and TYMV leaders produced a 6- and 5-fold stimulation, respectively (Table 3). The BMV RNA3 and "RSV" leaders provided only slight enhancement, 3- and 2-fold, respectively. Surprisingly, the Ω'-SPS leader sequence was much less stimulatory than Ω'-U1 in *E. coli*, causing only a 2-fold enhancement.

DISCUSSION

Work carried out by Kozak (6) showed that the initiation codon context of eukaryotic mRNAs has an important role in determining the selection of a particular start site and the level of mRNA expression. Our results from protoplasts, using two variants of GUS mRNA with either a "good" or "bad" initiation codon context, support these earlier findings (6).

The endogenous level of GUS activity in tobacco mesophyll protoplasts is extremely low. Thus we were able to quantitate accurately the stimulatory effect of Ω'-U1 and the other viral leaders on expression of GUS mRNA. Whether using "good" or "bad context" GUS mRNA, the presence of Ω'-U1 at the 5′-end resulted in a substantial enhancement of expression (approximately 20-fold; Table 1). When capped mRNAs were used (Table 1), the final level of enhancement by Ω'-U1 with "bad context" GUS mRNA, was greater than 60-fold and, with "good context" GUS mRNA, greater than 320-fold over that seen with the respective GUS mRNAs lacking both a cap and an Ω'-U1 sequence. Similar levels of enhancement were observed with Ω'-SPS (Table 2). In contrast, none of the other viral leader sequences were stimulatory with uncapped GUS mRNAs (Table 2). However, with capped GUS mRNAs, the leader sequences of AlMV RNA4, BMV RNA3, and "RSV" gave a 8-fold enhancement (Table 2). Only the TYMV leader failed to enhance, irrespective of whether the GUS mRNA was capped or not. It is of interest to note that the TYMV leader has been shown to form disomes (14), suggesting that the ability of a leader sequence to form disomes does not correlate with its ability to enhance translation. Alternatively, the 12 additional 5′-nucleotides added by our SP6 vector construct (7), may have selectively destroyed the ability of the TYMV leader to enhance translation. However, it appears that even in the absence of

these additional 5′-nucleotides, the TYMV leader sequence fails to stimulate translation (L. Gehrke, personal communication). *In vivo*, it may be that the TYMV leader is extremely host-dependent in its enhancing ability. Therefore even protoplasts made from tobacco mesophyll cells do not provide the proper machinery for the TYMV sequence. Certainly the ability of a viral leader sequence to enhance translation is not strictly dependent on its capacity to bind more than one ribosome, as shown by data (above and (18)) with the leader of AlMV RNA4 (a monosome former).

Translational enhancement of CAT mRNA by Ω'-U1 in microinjected oocytes was shown previously (7). In this report, enhancement was also observed with the related Ω'-SPS sequence. In contrast, leader sequences from AlMV RNA4, BMV RNA3 and "RSV" failed to enhance translation of CAT mRNA in oocytes. The TYMV leader construct reduced CAT mRNA expression by 80%.

The enhancing effect of Ω'-U1 in *E. coli* cells may be due to some fortuitous interaction with the prokaryotic translation machinery. However, as Ω'-U1 is devoid of G-residues, it cannot provide a sequence similar to that described by Shine and Dalgarno; (5′-AGGAGGU-3′; (1)) and shown to be present in, and required for efficient expression of, nearly all *E. coli* mRNAs studied to date. Of the other viral leaders, only those from TYMV and AlMV RNA4 displayed any significant enhancement of GUS activity in transformed *E. coli* cells.

In this survey of viral RNA leader sequences, only one, TYMV, consistently failed to enhance expression in the plant protoplast system. All the leader sequences were derived from positive-sense RNA viruses which must express their genetic information immediately and efficiently within the infected plant or animal cell to avoid the risk of degradation by host RNases. Furthermore, they must compete effectively with the endogenous cellular mRNAs.

Sequence comparisons between the leaders tested here show no significant homologies other than a high A,U-content, a common feature of viral leader sequences. It is tempting to speculate that the viral leader sequence may circumvent the need for some rate-limiting initiation factor(s), or that it acts as an enhancing element for the association of ribosomes or initiation

factor(s). A precedent for the former possibility exists in the translational regulation of the prokaryotic IF3 gene (32). The sequence immediately surrounding the IF3 start codon allows 30S ribosomal subunits to bind, and translation to begin, without a requirement for IF3, an initiation factor normally essential for the initiation process. The findings of Yokoe and co-workers (13) suggest, at least for the two TMV leaders tested, that a eukaryotic equivalent of the S-D region exists to interact with the 3′-end of 18S rRNA. The lack of homology between the various viral leader sequences may indicate that no one strategy is followed by all, but that there may be several ways to achieve enhancement.

The high A,U-content of these leaders might suggest a low index of secondary structure, which would present fewer obstacles to scanning (4,6) by eukaryotic ribosomes. However, the weak but stable secondary structure potential of the BMV RNA3 leader (2), and the potential of the complete RSV leader to form extensive secondary structures (3), have been used to explain how the 5′-cap and the initiation codon are juxtaposed to facilitate ribosome binding and translation initiation.

The affinity of these sequences for translation initiation factors or other mRNA-binding proteins remains to be tested. Clearly substantial additional work is required to elucidate the mechanism(s) whereby these viral leader sequences can enhance expression of contiguous coding regions in such diverse translation systems.

ACKNOWLEDGEMENTS

We are grateful to Peter Watkins and Clive Mason for excellent technical assistance, Muriel Hobbs for typing the manuscript and staff at the Institute of Animal Physiology, Babraham, Cambridge, U.K., for oligodeoxyribonucleotide synthesis. We also thank Richard Jefferson and Michael Bevan for pRAJ235 and pRAJ275. This work was funded by Diatech Ltd., London. Communicated by J. Schell

We have determined the complete primary structure (13 637 bp) of the TL-region of *Agrobacterium tumefaciens* octopine plasmid pTiAch5. This sequence comprises two small direct repeats which flank the TL-region at each extremity and are involved in the transfer and/or integration of this DNA segment in plants. TL-DNA specifies eight open-reading frames corresponding to experimentally identified transcripts in crown gall tumor tissue. The eight coding regions are not interrupted by intervening sequences and are separated from each other by AT-rich regions. Potential transcriptional control signals upstream of the 5′ and 3′ ends of all the transcribed regions resemble typical eukaryotic signals: (i) transcriptional initiation signals ('TATA' or Goldberg-Hogness box) are present upstream to the presumed translational start codons; (ii) 'CCAAT' sequences are present upstream of the proposed 'TATA' box; (iii) polyadenylation signals are present in the 3′-untranslated regions. Furthermore, no Shine-Dalgarno sequences are present upstream of the presumed translational start codons.
Key words: Agrobacterium tumefaciens/T-DNA/nucleotide sequence

Introduction

One of the remarkable properties of the Ti plasmids of *Agrobacterium* is their natural capacity to transfer, insert, and express a particular DNA segment of the Ti plasmid in plant cells (for recent reviews, see Nester and Kosuge, 1981; Bevan and Chilton, 1982; Caplan *et al.*, 1983; Zambryski *et al.*, 1983). Depending on the host plant and on the nature of Ti plasmid present in the inciting *Agrobacterium* strain, the transformation event results in crown gall or hairy-root or woolly-knot disease (see Kahl and Schell, 1982).

The segment of Ti plasmid DNA which becomes stably inserted in the plant genome is called T-DNA (Chilton *et al.*, 1977; Lemmers *et al.*, 1980; Thomashow *et al.*, 1980). On the Ti plasmid this DNA segment is bordered by two direct-repeat sequences of 25 bp (Zambryski *et al.*, 1982, 1983; Yadav *et al.*, 1982; Holsters *et al.*, 1983). In the case of the octopine Ti plasmids, two regions of the Ti plasmid, called TL (T-left) and TR (T-right) (Thomashow *et al.*, 1980) according to their position on the standard octopine Ti plasmid map (De Vos *et al.*, 1981) can be transferred and inserted independently into the plant genome. The TL-DNA has been studied more extensively because it encodes essential functions involved in the neoplastic transformation of plant cells (De Beuckeleer *et al.*, 1981; Garfinkel *et al.*, 1981; Leemans *et al.*, 1982; Willmitzer *et al.*, 1982). The TL-DNA also comprises the functions found in common between octopine-type and nopaline-type Ti plasmids' T-regions (Depicker *et al.*, 1978; Chilton *et al.*, 1978; Engler *et al.*, 1981; Willmitzer *et al.*, 1983).

Recently, the nucleotide sequence of the octopine synthase gene (De Greve *et al.*, 1982a), of the gene for 'transcript 7' (Dhaese *et al.*, 1983), and of the gene for 'transcript 4' (Heidekamp *et al.*, 1983) were determined. Here we present the complete nucleotide sequence of the TL-DNA of the *Agrobacterium tumefaciens* plasmid pTiAch5.

Results and Discussion

Sequence determination

To determine the complete sequence of the octopine TL-region, different plasmids containing subfragments of the TL-DNA were constructed (Table I) from clones pGV0153 and pGV0201 (De Vos *et al.*, 1981) containing fragments *Bam*HI-8 and *Hin*dIII-1 (Figure 1), which overlap the complete TL-DNA region. Detailed physical maps of these subclones were established to facilitate the nucleotide sequencing. Plasmid DNA was cleaved with a particular restriction enzyme, and the resulting fragments were ^{32}P end-labeled either at their 5′ termini with polynucleotide kinase or at their 3′ termini with the Klenow fragment of DNA polymerase I. After strand separation or secondary restriction to separate the labeled extremities, the sequence was determined by the limited chemical cleavage method of Maxam and Gilbert (1980). Both DNA strands were sequenced to avoid mistakes that could occur in regions with a distinct secondary structure or by incorrect reading and processing of the sequence information. In addition, as methylated bases (Ohmori *et al.*, 1978) can interfere with correct reading of the sequence, all *Eco*RII sites located in the TL-region were used for sequencing. Furthermore, care was taken that all restriction sites used to generate fragments were resequenced by using another fragment containing an alternative site. Figure 2 gives an overview of the sequence strategy.

Sequence analysis

An uninterrupted sequence of 13 637 bp including the whole TL-DNA of pTiAch5 was determined, and is displayed in the conventional orientation in Figure 3. The numbering starts at the *Hin*dIII site bordering fragments 14 and 18c, which is located 308 bp to the left of the left TL-DNA terminus sequence.

Termini sequences. The TL-region is flanked at both extremities (position 308 and 13 459) by direct repeats of 24 bases, which are believed to be important for the transfer of the TL-DNA segment (Zambryski *et al.*, 1982; Simpson *et al.*, 1982; Holsters *et al.*, 1983).

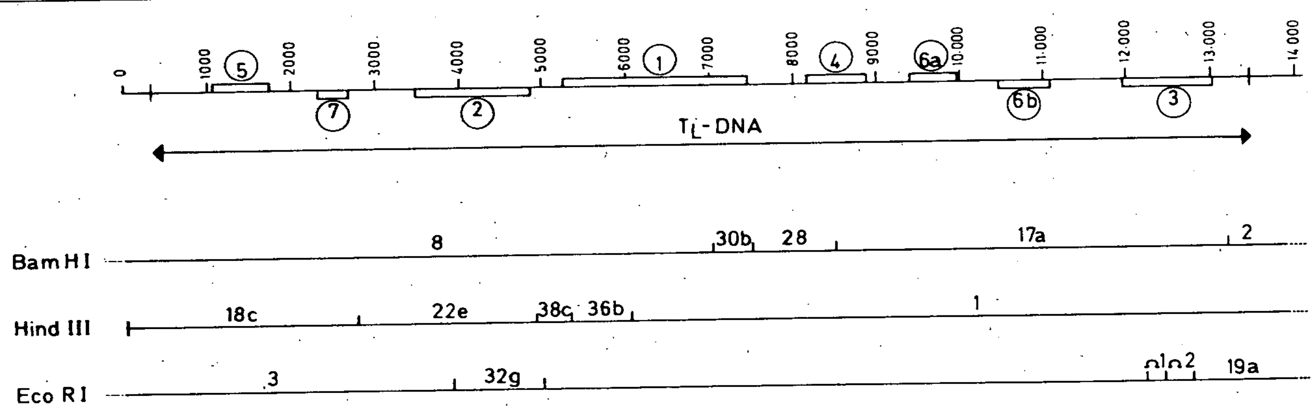

Fig. 1. Restriction map of the TL-DNA of the octopine Ti plasmid pTiAch 5. **Upper portion**: the position of the open-reading frames are presented by open boxes and numbered according to Willmitzer *et al.* (1982). The polarity of the open-reading frames is indicated as follows: open boxes above the line are transcribed from left to right and open boxes below the line are transcribed from right to left. The extent of the TL-DNA is indicated by an arrow and is delimited by the termini boxes (heavy vertical bars). **Lower portion**: a restriction map of the TL-DNA region is shown for the restriction enzymes *Bam*HI, *Hind*III, and *Eco*RI.

A computer search of the complete TL-region for DNA sequences displaying homologies with these direct repeats revealed 10 related DNA sequences. These sequences are listed in Table II. Genetic and physical data indicate that some of these sequences might also be used *in vivo* during transfer and integration of the TL-DNA. Firstly, the sequence (position 11 798) present in the 3′-untranslated region of the octopine synthase gene has been noted by Holsters *et al.* (1983). If this sequence is recognized as a left terminus sequence, the presence of the abbreviated T-DNA found in the octopine-positive regenerate plants rGV1 and rGV5 (De Greve *et al.*, 1982b) can be explained. Alternatively, if this sequence is recognized as a right terminus sequence, instead of the normal terminus sequence, tumor lines containing a shorter TL-DNA which do not synthesize octopine (Thomashow *et al.*, 1980; De Beuckeleer *et al.*, 1981; Ooms *et al.*, 1982) are formed. The origin of teratomas (unpublished results) expressing transcripts 4, 6a, 6b, octopine synthase, and possibly transcript 1, can be explained if the sequence (position 3750) located in transcript 2 is used as a left terminus sequence. Similarly, an abnormal plant (unpublished data) possibly containing transcript 4 and expressing the octopine synthase gene, could be explained if the sequence (position 7777) is used as a left terminus sequence. In addition, either the sequences at position 9078, 10 131, or 10 603 if used as a right terminus sequence, could explain the short TL-DNA observed in a *Petunia* tumor line P-Ach5 (De Beuckeleer *et al.*, 1981). Whether the other sequences also signalled the creation of abbreviated TL-DNAs is difficult to answer because in most cases the resulting transferred DNA

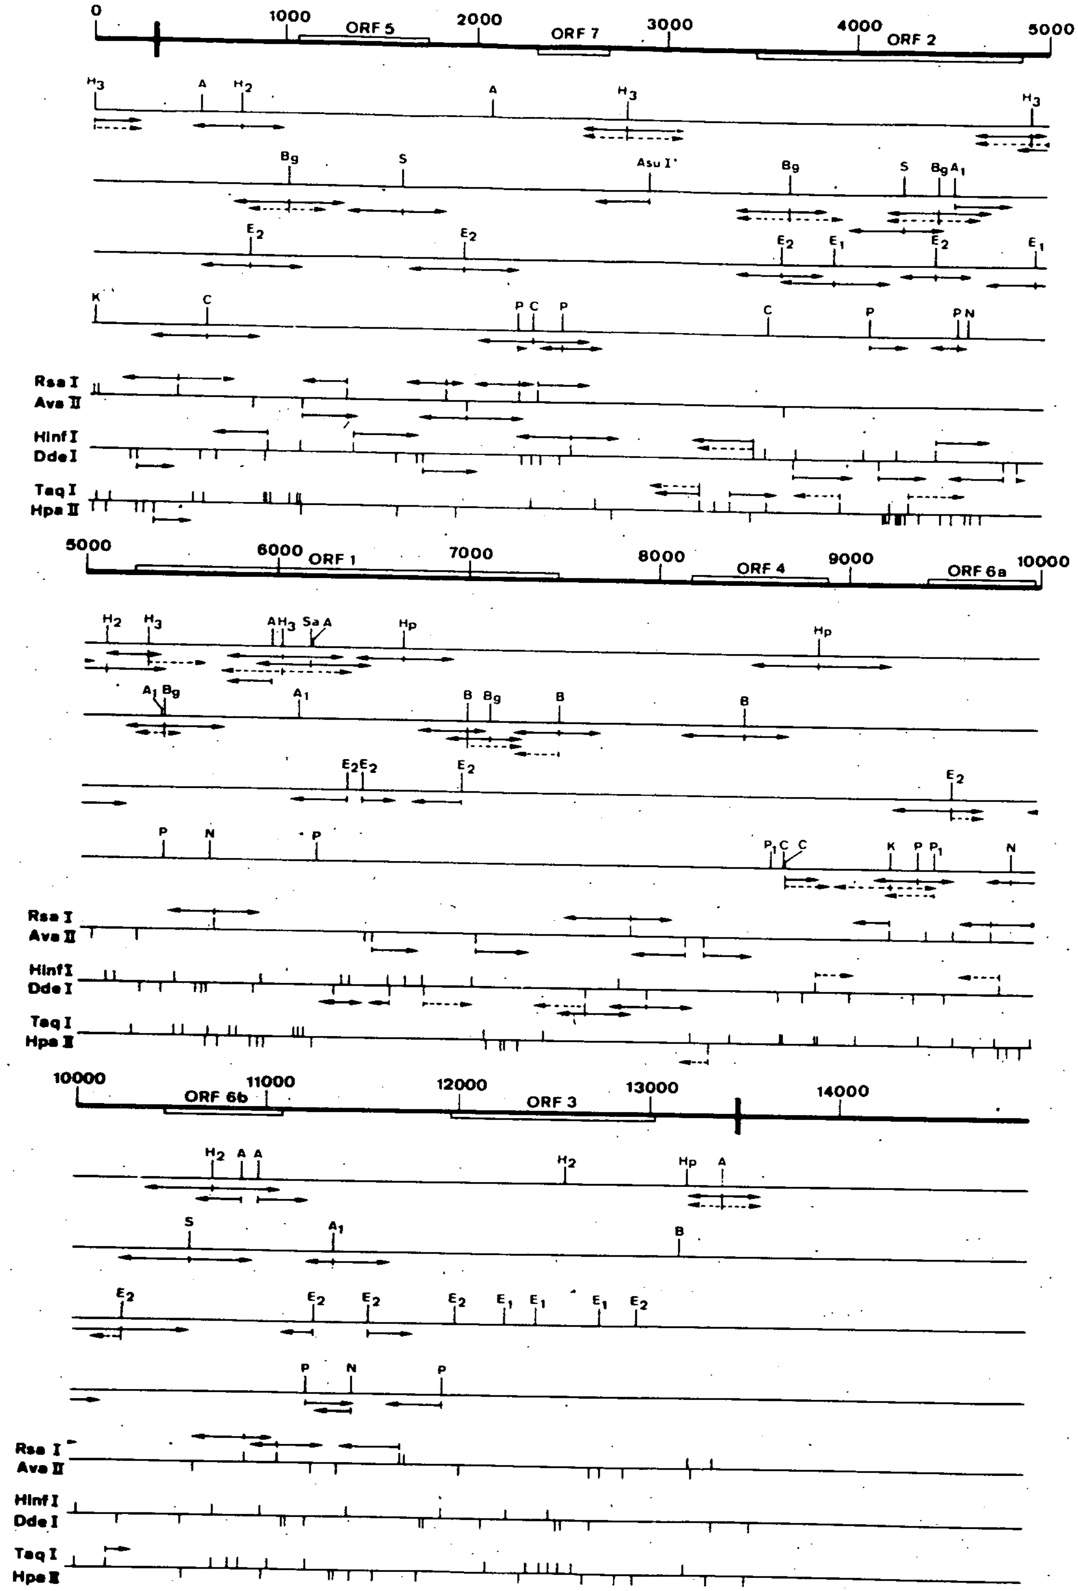

Fig. 2. Sequencing strategy. On a map of the TL-region of pTiAch5 the restriction sites for the following enzymes have been indicated: A, *Acc*I, A1, *Ava*I; Bg, *Bgl*II; C, *Cla*I; E1, *Eco*RI; E2, *Eco*RII; H2, *Hind*II; H3, *Hind*III; Hp, *Hpa*I; K, *Kpn*I; N, *Nae*I; P, *Pvu*II; P1, *Pst*I; S, *Sma*I; Sa, *Sal*I. The position and extent of each sequencing experiment is indicated by a full arrow for a 5′ to 3′ sequencing, and a dashed one for 3′ to 5′. Termini boxes are indicated by a heavy bar, and the open-reading frames corresponding to plant transcripts by open boxes. The polarity of the open-reading frames is indicated from left to right by drawing the open boxes above the line and from right to left by drawing the open boxes below the line.

Figure 3(iii)

Fig. 3. Complete nucleotide sequence of the TL-region of pTiAch5. An uninterrupted sequence of 13 637 bp starting at the *Hind*III site bordering the fragments 14 and 18c covers the whole TL-region. The sequence is displayed in the conventional orientation along with the translation in amino acids for the coding sequences for which experimental evidence exists. The amino acid sequence is above the DNA sequence when transcription occurs from left to right, and below the sequence for the other orientation. The two direct repeats present at both extremities of the TL-DNA are indicated by a closed box. The mRNA start and the polyadenylated sites and signals of transcripts 3, 4 and 7 are indicated by an arrow. The polyadenylation signals of transcripts 3 and 7 are underlined and their polyadenylation sites are indicated by an asterix.

would not produce an easily detected altered phenotype in the transformed plant cells.

Size and position of coding sequences. The sequence between the 24-bp direct repeats was analyzed for possible translational open-reading frames. The 18 largest open-reading frames are presented in Table III. To evaluate which of these open-reading frames are actually used *in vivo*, their position was compared with the known positions of TL-DNA transcripts in octopine crown gall tissues (Willmitzer *et al.*, 1982). Seven of the open-reading frames did correspond with known transcripts. We tested whether or not some of the other open-reading frames might correspond to TL-DNA regions, whose transcripts might have gone undetected, by comparing their position with empty regions in the transcription map. This was the case only for open-reading frame m (Table III). Subsequently, a careful experimental analysis confirmed that this open-reading frame corresponded to an actual transcript (6b) (Willmitzer *et al.*, 1983; Joos *et al.*, 1983). The translation of these eight open-reading frames in amino acids is presented in Figure 3 and their codon usage is listed in Table IV. It was also tested whether open-reading frame p which is derived from the opposite strand of transcript 3 and which might code for a protein of 142 amino acids could correspond to an actual transcript. M13 mp2 phage DNA, containing the small *Eco*RI fragments Ω_1 and Ω_2 (Figure 1) located in the octopine synthase gene, were separately applied on nitrocellulose and hybridized with labeled mRNA isolated from tobacco crown gall tissues. Only the phage DNA spot containing the strand corresponding to transcript 3 (octopine synthase) hybridized with mRNA (data not shown).

We have applied the RNY algorithm described by Shepherd (1981) on the whole sequence of the TL-DNA (data not shown). Eight frames were detected and these correspond to the eight known transcribed regions.

The size and map position of several proteins, expressed by the T-DNA in transformed plant cells, or by the T-region in bacterial cell-free systems, have been recently determined (summarized in Table III). By hybridization selection and translation of T-DNA-encoded mRNA from octopine tumors, three proteins of 39, 27 and 14 kd were detected (Schröder and Schröder, 1982). The largest has been shown to

Table II. DNA sequences homologous to the 24-bp termini sequences

The table displays all the open-reading frames larger than 75 amino acids. The co-ordinates are those of the first nucleotide following the preceding stop, the last nucleotide of the stop codon and the A of the first ATG in frame. The length of the deduced protein (expressed in amino acids, ΣAA) and its mol. wt. has been calculated and is compared, when possible, with experimental data (Schröder and Schröder, 1982; Schröder *et al.*, 1981, 1983).

There is no general bias in the codon usage of these eight coding sequences taken together, although individually, large deviations do occur. We should note that the transcripts 1, 2, 3, 6a and 6b have a high preference for G as first base (>33.9%) and transcripts 4, 6a, 6b and 7 have a high percentage of A in the second position (>33.2%). No such deviations are noted in the third position.

be octopine synthase (transcript 3). The smallest one was selected with *Hind*III fragment 18 (Figure 1) and corresponds to the translated part of the gene transcript 7. The nucleotide sequences of both transcript 3 and 7 have been described (De Greve *et al.*, 1982a; Dhaese *et al.*, 1983). The third protein (mol. wt. = 27 kd) was observed after hybridization selection both with the partially overlapping fragments *Bam*HI-8 and *Hind*III-1 (Schröder and Schröder, 1982) (Figure 1). The authors suggested that at least part of the coding region is common to both fragments, but we do not find any open-reading frame in this part of the TL-region corresponding to a protein of this size. However, from Table III it appears that the polypeptides encoded by transcript 4 (located in *Hind*III fragment 1; Figure 1) and transcript 5 (located in *Bam*HI fragment 8; Figure 1) have nearly the same mol. wts. (26 873 and 25 635 daltons, respectively). The experimental results obtained by Schröder and Schröder (1982) can be explained if we assume that the observed 27-kd protein bands are in fact different and are encoded by transcripts 4 and 5, respectively.

The TL-region of octopine Ti plasmids expresses four proteins (mol. wt. = 74, 49, 28 and 27 kd) in *Escherichia coli* mini-cells (Schröder *et al.*, 1983). A comparison of the regions expressed in bacteria and the TL-region sequence indicates that three protein-coding regions in the bacteria correspond to three open-reading frames which are transcribed in plants (Table III). The mol. wts. of the polypeptides encoded by transcripts 2 (49 kd) and 4 (27 kd) as calculated from the sequence, are in good agreement with the mol. wts. experimentally observed by Schröder *et al.* (1983) in a bacterial background. However, there is a discrepancy between the calculated (84 kd) and the observed (74 kd) mol. wts. for the protein encoded by transcript 1. Schröder *et al.* (1983) showed that the right-end of the *Bam*HI-8 fragment (Figure 1) in pGV0153 encoded a 66-kd protein, which represents a shortened form of the 74-kd protein. The mol. wt. of this shortened protein calculated from the DNA sequence is 69 kd. Furthermore, deletion of fragment *Hpa*I-14, which is an internal fragment of *Eco*RI fragment 7 (Figure 1) that covers this region, produced a protein of mol. wt. = 53 kd (Schröder *et al.*, 1983). From the DNA sequence we can predict that the first 483 amino acids of transcript 1 will be fused to the last 16 amino acids of transcript 4 in this deletion mutant. The mol. wt. of this fusion protein is 55 kd, in good agreement with the mol. wt. (53 kd) observed by Schröder *et al.* (1983). It is likely, therefore, that the 74-kd protein is indeed encoded by the transcript 1 gene and that the difference in the observed and calculated mol. wts. can be explained by (i) an underestimation of the observed mol. wt. in SDS-polyacrylamide gels, or (ii) proteolytic degradation of this polypeptide in bacteria yielding a shorter protein.

Finally, Schröder *et al.* (1983) observed a 28-kd polypeptide in *E. coli* mini-cells. They located the gene encoding this polypeptide to the left of transcript 4. We do not find an open-reading frame in this region large enough to accommodate this 28-kd protein. Furthermore, no mRNA isolated from crown gall tumors has been observed to hybridize to this region.

Transcription initiation and polyadenylation signals. Comparisons of a multitude of eukaryotic protein-encoding genes have revealed a limited number of consensus sequences potentially involved in RNA polymerase II-mediated transcription. The 'TATA' box or Goldberg-Hogness box (Proudfoot, 1979) is located 25–30 bp upstream from the start site of transcription and is involved *in vivo* in the accurate positioning of the mRNA start site (McKnight and Kingsbury, 1982). The consensus sequence GG(C/T)CAATCT of 'CCAAT' box (Benoist *et al.*, 1980), which appears 40–50 nucleotides upstream of the TATA box, is involved in the regulation of transcription of some eukaryotic genes. By comparing plant genes, a possible regulatory sequence, called AGGA box, was identified by Messing *et al.* (1983). As the transcription of TL-DNA genes is α-amanitin sensitive (Willmitzer *et al.*, 1981) and potential control signals in the 5′ regions of the T-DNA genes (De Greve *et al.*, 1982a; Depicker *et al.*, 1982; Dhaese *et al.*, 1983; Heidekamp *et al.*, 1983), of which the transcription initiation site was accurately determined, have been found resembling those typically used by eukaryotes, we

searched for homologies with these putative regulatory sequences in the 5′-untranslated region of the TL-DNA genes. In the 5′-untranslated region of transcript 5, three sequences AATAATA, TATAAGA, and TTTATAT (position 983, 1012 and 1029), sharing homology with the TATA sequence, are located respectively 77, 48 and 31 bp upstream from the translation start codon and are preceded by four 'CCAAT'-like sequences (GGCGAATAT at position 909, ACGCAATTA at 935, TACCAATAA at 979, GGCCATTTA at 1001). Transcript 2 has a TATATTT sequence (position 3460) and two possible CCAAT sequences (GCGCAAGCT at position 4932 and CACCAATAA at 4943). A TATTTAT sequence (position 5175) is located 34 bp upstream from the translation start codon of the gene encoding transcript 1. This TATA box is preceded by three possible CCAAT boxes (positions 5692, 5118, and 5114). The 5′-untranslated region of the gene encoding transcript 6a contains a TATTAAT sequence (position 9326) located 69 bp upstream from the ATG translation codon and a CCAAT sequence (position 9294) located 32 bp upstream from the presumed TATA box. The gene encoding transcript 6b has a TATAAAA sequence (position 11 137) 61 bp upstream from the translation start codon. Two CCAAT sequences (position 11 169 and 11 204) are located upstream of the TATA box at a distance of 32 bp and 67 bp. A summary of the eukaryotic signals found in the 5′-untranslated regions is listed in Table V. However, we did not find sequences in the 5′-untranslated regions of the TL-DNA sharing significant homology with the AGGA box (Messing *et al.*, 1983).

Sequences essential for the *in vivo* expression of eukaryotic genes, however, are located, in most cases, 200–300 bp upstream of the transcription initiation site. From genetic studies, there is evidence that sequences upstream of the TATA and CCAAT boxes are also involved in the *in vivo* expression of the octopine synthase gene (Koncz *et al.*, 1983) in plant cells. We did not find nucleotide sequence homology between this 5′ upstream region of the octopine synthase gene and the 5′ upstream regions of the other TL-DNA genes.

Most eukaryotic protein-encoding transcripts are polyadenylated. The only primary sequence common to the 3′-untranslated region of almost all eukaryotic genes is the hexanucleotide AATAAA (Proudfoot and Brownlee, 1976; Benoist *et al.*, 1980), or a one-base variation of this sequence (Nevins, 1983). This sequence functions in the recognition of the poly(A) addition site (Fitzgerald and Shenk, 1981; Montell *et al.*, 1983). The poly(A) addition sites of the octopine synthase (De Greve *et al.*, 1982a), the nopaline synthase (Depicker *et al.*, 1982), the octopine synthase present in the regenerated plant rGV1 and transcript 7 (Dhaese *et al.*, 1983) are indeed closely preceded by this hexanucleotide signal. In the case of the wild-type octopine synthase and the rGV1 octopine synthase multiple polyadenylation sites have been observed. This was also found to occur in animal genes

(Setzer *et al.*, 1980; Early *et al.*, 1980). We looked for the presence of AATAAA or related sequences in the 3′-untranslated regions of the TL-DNA genes encoding transcripts 5, 2, 1, 6a and 6b. For each gene at least two potential canonical sequences are found. Transcripts 5 and 1 each contain two polyadenylation signals AATAAT (position 1912 and 1948 for transcript 5 and 7710 and 7727 for transcript 1). In transcript 5, these are located at a distance of 172 bp and 208 bp downstream of the stop codon, and those of transcript 1 at 234 bp and 251 bp downstream from the stop codon. The 3′-untranslated region of transcript 2 contains four possible polyadenylation signals: AATAAT (position 3281), AATAAT (3297), AATAAA (3312) and AATAAT (3364), respectively 96, 148, 163 and 180 bp, past the translational stop. In the 3′ region of transcript 6b three polyadenylation signals AATAAT (10 260), AATAAA (10 355), and AATAAA (10 434) are found respectively 193, 98 and 19 bp downstream from the stop codon. Transcript 6a has two sequences: TATAAA (10 030) and AATGAA (10 085) in its 3′ end which are located at a distance of 60 bp and 115 bp downstream from the stop codon. All these data are summarized in Table V.

Translation initiation codons. In eukaryotes, the first AUG of the majority of mRNAs is used as an initiation codon. In the scanning model, two bases (A or G at position −3, G at position +4) flanking the initiation codon (A/GXXAUGG) facilitate the recognition of the functional AUG codon (Kozak, 1981).

Since none of the amino acid sequences of the proteins encoded by the TL-DNA in plant cells have been determined, no experimental data exist concerning the sites used to initiate translation of the plant transcripts. As can be seen in Figure 2, the first AUG following the 'TATA' box is in phase with all the open-reading frames and most likely initiates translation in plants. The first AUG of these plant transcripts are preceded by a very G-poor stretch of DNA and do not contain a Shine-Dalgarno sequence (Shine and Dalgarno, 1974; Stormo *et al.*, 1982). This lack of Gs upstream of eukaryotic initiation codons has already been observed (Kozak, 1981; Sargan *et al.*, 1982).

In the open-reading frames of the genes encoding transcript 5, 7, 2, 4 and 3 the second AUG is located at a distance of 300, 231, 354 and 252 bp, respectively, of the first AUG. In the case of open-reading frames 2 and 4, which are translated in *E. coli* mini-cells (Schröder *et al.*, 1983) these data support the hypothesis that the same translational start is used in bacteria as well as in plant cells. Two AUG codons (positions 11 019 and 11 076) can be used as initiation codon for transcript 6b. Both AUG codons are flanked by a G (position −3) and an A (position +4). Because the initiation codons are equivalent, there is no reason to believe that the first AUG codon is not used as the translational start.

In transcript 6a three AUG codons (position 9395, 9404 and 9410) can be used as initiation codon. The first and the third AUG codons are flanked by two bases which facilitate the recognition of functional AUG codons (Kozak, 1981). Comparison of the TL-DNA sequence of transcript 6a with the corresponding nopaline T-DNA sequence (unpublished data) indicate that in the homologous pTiC58 sequence only the third AUG is conserved. This observation suggests that translation of the octopine transcript 6a starts at the third AUG. However, we cannot exclude that the transcripts 6a encoded by the octopine TL-DNA and the nopaline T-DNA, respectively, have different translational starts.

Transcript 1 also contains three AUG condons in the beginning of the frame (positions 5209, 5260 and 5275). Although we have no data to support that the first AUG is not used as the initiation signal in the plant cells, the possibility exists that the third AUG, which is preceded by a GGTGGA sequence (position 5262) might be preferably used in a bacterial background. The difference in mol. wt. will be 2.3 kd, when calculated from the sequence, and the correspondence with the observed mol. wts. of the shorter polypeptides (53 and 66 kd) (Schröder *et al.*, 1983) and the computed mol. wts. (52.7 and 66.7 kd) are even better.

To solve the question of whether the same translation start codon is used in plant cells and in bacteria, amino acid sequences of both will be needed.

Intervening sequences. A characteristic but not an absolute criterion of eukaryotic genes is the presence of intervening se-

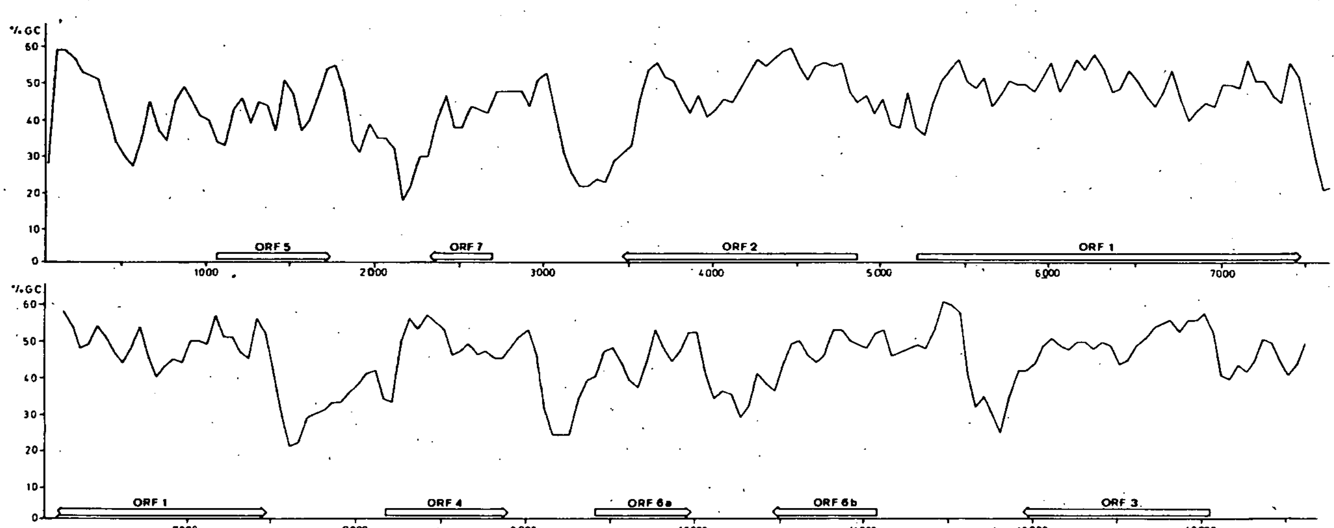

Fig. 4. GC profile of the TL-DNA. A window of 100 bp was slid along the sequence by increments of 50 bp, and its G+C percentage was calculated. The position and size of each known coding region and its orientation is indicated by arrows. The two parts of the figure are contiguous, but the right part of transcript 1 is repeated in the lower figure in order to emphasize the periodicity of the GC content.

quences. To date, several plant nuclear genes have been shown to contain intervening sequences (Sun *et al.*, 1981; Fisher and Goldberg, 1982; Hyldig-Nielsen *et al.*, 1982; Shah *et al.*, 1982), while several others lack intervening sequences (Geraghty *et al.*, 1981; Fisher and Goldberg, 1982; Pedersen *et al.*, 1982). The existence of introns in the coding regions of the different TL-DNA transcripts is very unlikely. Firstly, the open-reading frames correlate well with the sizes of the cytoplasmic polyadenylated transcripts 1, 2, 3, 4, 5, 6a, 6b and 7, determined by Northern analysis (Willmitzer *et al.*, 1982, 1983). Secondly, as discussed above, the sizes of the proteins observed experimentally *in vitro* (Schröder and Schröder, 1982), and in *E. coli* (Schröder *et al.*, 1983) correspond nicely to those calculated from the sequence presented in Figure 3. Furthermore, we have looked without success for sequences fitting with the donor and acceptor consensus sequences proposed by Mount (1982) normally found at the intron-exon junctions.

G+C content. A striking feature of the TL-DNA sequence (Figure 4) is observed when a graphical display of a G+C content profile is plotted. Each functional coding sequence is separated from its neighbours by an AT-rich interval. The 3′-untranslated region of each transcript is very AT-rich, a feature also observed in the 3′-untranslated region of other plant genes, ranging from 24% G+C in the soybean leghemoglobin gene (Hyldig-Nielsen *et al.*, 1982) to 37% G+C in the ribulose-1,5-biphosphate carboxylase gene (Bedbrook *et al.*, 1980). The dip in the G+C profile is less marked between transcripts 1 and 2, possibly because in this case both 5′ ends are very close to one another. Furthermore, these large variations of G+C content can be visualized under the electron microscope by partial denaturation of the Ti plasmid and are limited to the TL-region and the homologous region of the nopaline T-DNA (G. Engler, personal communication).

Conclusions

From the determination and the analysis of the primary structure of the TL-DNA sequence, the following conclusions can be drawn: (i) all the TL-DNA genes contain the signals to be transcribed and translated in plant cells; (ii) the absence of intervening sequences and the compact organization of the genes on the TL-DNA suggest that a maximum amount of genetic information is concentrated in a minimum amount of DNA.

Materials and methods

Enzymes

DNA polymerase I (large fragment, according to Klenow) and T4 polynucleotide kinase were from Boehringer Pharma (Mannheim, FRG).

Restriction enzymes were from Boehringer Pharma (Mannheim, FRG) or New England Biolabs (Beverly, MA, USA), and were used according to the suppliers' instructions.

Bacterial strains and plasmids

Bacterial strains and plasmids are listed in Table I.

Plasmid preparation

Agarose gel electrophoresis, conditions for DNA ligation, and transformation of competent *E. coli* cells were as described by Depicker *et al.* (1980).

Plasmids were prepared from *E. coli* K514 or by CsCl-EtBr equilibrium density gradient centrifugation in cleared SDS lysates (Betlach *et al.*, 1976). The copy number of the pBR derivatives was increased by adding chloramphenicol (170 μg/ml) or spectinomycin (300 μg/ml) to an exponentially growing culture and incubating for a further 15 h.

DNA sequence determination

DNA fragments to be sequenced were labeled at their 5′ ends with [γ-^{32}P]-ATP (>2000 Ci/mmol, Amersham) and T4 polynucleotide kinase (Boehringer, Mannheim, FRG) after treatment with bacterial alkaline phosphatase (Boehringer, Mannheim, FRG); DNA fragments wre labeled at their 3′ ends using either [^{32}P]cordycepin (NEN) and terminal nucleotidyl transferase, or [α-^{32}P]dATP and Klenow polymerase (Boehringer, Mannheim, FRG). The labeled fragments, after secondary restriction, were extracted from low-gelling temperature agarose as described by Wieslander (1979), or, after strand separation, were extracted from acrylamide as described by Maxam and Gilbert (1980).

The five chemical modification and cleavage reactions G, A+G, C+T, C and A+C were performed as described by Maxam and Gilbert (1980). The cleavage products were separated on 8% and 15% gradient acrylamide gels (0.3 mm x 90 cm) containing 8.3 M urea (Sanger and Coulson, 1978). The gels were autoradiographed at −70°C using intensifying screens.

Computer analysis

Routine analysis (restriction sites, overlaps) of the sequencing data was performed on a Cromemco microcomputer using the mapping and comparison programs written by Schroeder and Blattner (1982) for the CP/M operating system. We developed a program along the lines of the RNY algorithm, described by Shepherd (1981) and the programs used to calculate the mol. wt. of the proteins (Table II), the codon usage (Table III), and the GC profile of the sequence (Figure 4). The limited computing ability of our microcomputer did not allow us to perform extensive searches of similarities using the Sellers (1979), or Needleman and Wunsch (1970) algorithms. Imperfect repeats might therefore have escaped. A machine-readable copy of the sequence has been sent for incorporation in the EMBL data base.

Acknowledgements

The authors wish to thank Ms M. De Cock for typing the complete nucleotide sequence and the manuscript, and K. Spruyt and A. Verstraete for photographical work. This research was supported by grants of the 'ASLK-Kankerfonds', 'Fonds voor Geneeskundig Wetenschappelijk Onderzoek' (FGWO 3.0001.82), 'Instituut tot aanmoediging van het Wetenschappelijk Onderzoek in Nijverheid en Landbouw' (IWONL 3849A), and the Services of the Prime Minister (OOA 12052179), and was carried out under Research Contract No. GBI-4-017-B(RS) of the Biomolecular Engineering Programme of the Commission of the European Communities.

Abstract

The effects of subcellular localization on single-chain antibody (scFv) expression levels in transgenic tobacco was evaluated using an scFv construct of a model antibody possessing different targeting signals. For translocation into the secretory pathway a secretory signal sequence preceded the scFv gene (scFv-S). For cytosolic expression the scFv antibody gene lacked such a signal sequence (scFv-C). Also, both constructs were provided with the endoplasmic reticulum (ER) retention signal KDEL (scFv-SK and scFv-CK, respectively). The expression of the different scFv constructs in transgenic tobacco plants was controlled by a CaMV 35S promoter with double enhancer. The scFv-S and scFv-SK antibody genes reached expression levels of 0.01% and 1% of the total soluble protein, respectively. Surprisingly, scFv-CK transformants showed considerable expression of up to 0.2% whereas scFv-C transformants did not show any accumulation of the scFv antibody. The differences in protein expression levels could not be explained by the steady-state levels of the mRNAs. Transient expression assays with leaf protoplasts confirmed these expression levels observed in transgenic plants, although the expression level of the scFv-S construct was higher. Furthermore, these assays showed that both the secretory signal and the ER retention signal were recognized in the plant cells. The scFv-CK protein was located intracellularly, presumably in the cytosol. The increase in scFv protein stability in the presence of the KDEL retention signal is discussed.

Introduction

Recent advances in antibody engineering offer various perspectives to endow plants with new properties. Antibodies and antibody fragments can be used to engineer disease resistance, to alter or design metabolic routes with catalytic antibodies, and to study plant growth and develop-

ment by antisense-like approaches [32]. For these applications it is crucial to have functional antibodies located in the proper subcellular compartment. This can be accomplished by providing the antibody with suitable targeting and sorting signals [1].

The engineering of antibodies is facilitated by their domain structure. The domains carrying the antigen-binding loops can be manipulated in different ways to create various biologically active fragments [42]. An interesting and valuable antibody fragment is the single-chain antibody (scFv), in which the variable domains of light and heavy chain are connected by a flexible peptide linker. Through expression of scFvs, several problems inherent to the post-translational processing of complete antibodies, such as assembly of the four subunits, formation of intermolecular disulphide bonds and glycosylation, can be circumvented [15, 17].

Single-chain antibodies have been successfully expressed in plants. Constitutive cytosolic expression of an scFv antibody in tobacco mediated resistance against artichoke mottled crinkle virus [36]. Owen *et al.* [27] and Firek *et al.* [11] reported cytosolic expression and secretion of an anti-phytochrome scFv antibody.

Cytosolic expression of functional scFv antibodies in plants and other eukaryotes [2, 3, 41] is remarkable. The two intramolecular disulphide bridges (one in V_H and one in V_L) which are assumed to be necessary for folding into a stable and functional scFv [14] are expected not to be formed in the reducing environment of the cytosol because of the absence of the enzyme protein disulphide isomerase [13], which catalyses the formation of such bonds.

Despite the reported successes, intracellular expression of scFv antibodies in plants may not be that straightforward. Owen *et al.* [27] reported that only after screening more than 100 transgenic plants, transformed with 'leaderless' scFv constructs, a plant showing an expression level of 0.1% of the total soluble protein fraction was obtained, while transformants expressing the secretory version of the scFv gene produced ten times more scFv protein [11].

The objective of our study was to compare functional expression of scFv proteins in transgenic tobacco plants if targeted to different subcellular compartments. The scFv gene was derived from the heavy and light chain genes of an antibody raised against a cutinase (21C5) of *Botrytis cinerea* [29]. Both with and without signal peptide the expression of this scFv gene greatly improved when the C-terminal endoplasmic reticulum (ER) retention signal peptide, KDEL [28], was added. Possible causes for this strong enhancement of expression and the implications for antibody expression in plants are discussed.

Materials and methods

Bacterial vectors and strains

For cloning of the scFv inserts the bacterial expression vector pHEN1 [19] was modified by substituting the multiple cloning site and deleting the g3p gene (pNEM5). Addition of the KDEL (Lys-Asp-Glu-Leu) coding sequence behind the c-myc tag sequence resulted in pNEM5K. The *Escherichia coli* strains DH5α and TG1 were used for routine cloning and scFv protein expression, respectively.

Plant vectors

The vectors pCPO33, pCPO33T and pCPO35 were used for plant transformations and transient assays. These vectors are closely related to pCPO5 [12] and only differ between the T-DNA borders (Fig. 1). The vector pCPO33 contains a promoter-terminator cassette composed of a truncated cauliflower mosaic virus (CaMV) Cabb B-D 35S promoter (−343/−1) with duplicated enhancer sequence (−343/−90) together with the 38 bp alfalfa mosaic virus (AlMV) RNA4 untranslated leader [33], a polylinker with unique *Nco*I, *Sst*I, *Sma*I and *Bgl*II cloning sites, and the nopaline synthase terminator, respectively. Furthermore, the β-lactamase gene for prokaryotic selection (ampicillin in *E. coli*, carbenicillin in *Agrobacterium tumefaciens*) and the APH(3′)II

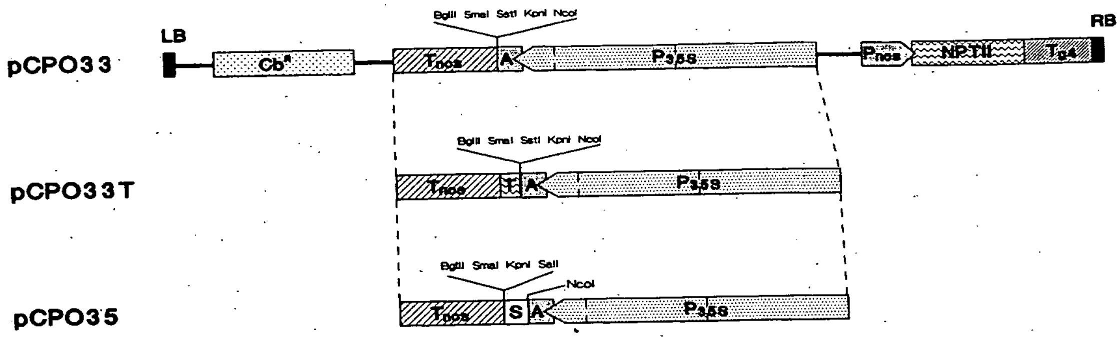

Fig. 1. T-DNA of pCPO33, pCPO33T and pCPO35. LB, left border; RB, right border; A, alfalfa untranslated leader; S, secretory signal sequence; T, c-myc tag; NPTII, neomycin phosphotransferase gene; Pnos, nopaline synthase promoter; Tg4, T-DNA gene 4 terminator; P35S, CaMV 35S promoter with doubled enhancer; Tnos, nopaline synthase terminator; Cb^R, carbenicillin resistance gene.

gene under the control of the nopaline synthase promoter for kanamycin resistance selection at the plant level were located between the T-DNA borders. pCPO33T contains a c-myc tag sequence [25] between the multiple cloning site and nopaline synthase terminator. pCPO35 contains a mouse kappa light chain signal sequence as *Nco*I-*Sal*I fragment between the 35S promoter and the *Kpn*I site. The mouse signal sequence for ER translocation is derived from the kappa light chain, CEA 66E3 [21, 37], and was chosen because minor changes could create a *Sal*I site, which is rare in antibody genes [5, 21]. The signal sequence was made synthetically with an *Nco*I site at the 5′ end (triplet position −24) and a *Sal*I site at the 3′ end (triplet position −3).

Isolation, amplification and cloning of antibody 21C5 variable domains

Isolation of poly(A)$^+$ RNA from 21C5 hybridoma cells [29] was performed by using the QuickPrep *Micro* mRNA purification kit (Pharmacia). First strand cDNA was synthesized using the Pharmacia First Strand cDNA Kit. The variable heavy (V_H) and light domains (V_L) of the 21C5 antibody were amplified through PCR using the following primers: 5′-end primer (H53) 5′-GGTCTCGAGTGTGAGGTCCAGCTGCAACAATCTG-3′ and 3′-end primer (VH33) 5′-ATGCGTTAACCCCGGGTGTTGTTTTGGCTGMRGAGACDGTGAS-3′ for the heavy chain, and 5′-end primer (L5d) 5′-GGTGTCGACGGTGATGTTKTGATGACCCAAA-3′ and 3′-end primer (VK1) 5′-GGCTCGAGTTTGGATTCGGAGCCGGATCCTGAGGATTTACCCTCCCGTTTTATTTCCAGSTTGGTSCCYCC-3′ for the light chain. Primers L5d and H53 contained a *Sal*I and *Xho*I site at their 5′-end, respectively. Primer VH33 was chosen such that, after PCR amplification and digestion with *Sma*I, the V_H domain still contained the initial five triplets of the CH1 domain, encoding Ala-Lys-Thr-Thr-Pro. The primer VK1 carried an *Xho*I site at the 5′-end. Primer VK1 also encodes a sequence for a synthetic linker peptide, adapted with some modifications from Chaudhary *et al.* [5]. For amplification first strand cDNA was denatured at 94 °C for 4 min and subjected to 35 cycles of PCR using Vent DNA Polymerase (New England Biolabs). Each PCR cycle consisted of denaturation at 94 °C for 1 min, annealing at 60 °C for 2 min, and primer extension at 72 °C for 3 min. The amplified fragments were purified from agarose gel, digested with the appropriate restriction enzymes, and ligated simultaneously into *Sal*I/*Sma*I-digested pNEM5 and pNEM5K, resulting in the vectors pNEM-scFv and pNEM-scFv-K, respectively.

The nucleotide sequences of the scFv inserts were verified by the dideoxy chain termination sequencing method [31] on an A.L.F. DNA sequencer (Pharmacia). The sequence encoding the 21C5 scFv was subjected to computer analysis with the Wisconsin GCG software package [9]. From the derived protein sequence the molecular weight was calculated and the algorithm for predicting processing sites for eukaryotic signal sequences was used [39].

Bacterial expression of scFv cassettes

E. coli strain HB 2151 was transformed with pNEM-scFv and pNEM-scFv-K. For the scFv expression assay 5 ml 2 × TY, 1% (w/v) glucose and 100 μg/ml ampicillin was inoculated with a colony containing the appropriate plasmid, and incubated at 30 °C for 16 h. Fresh medium containing 2 × TY, 0.075% (w/v) glucose and 1 μg/ml ampicillin was inoculated with 1/50 volume of the bacterial culture and incubated at 30 °C for 3 h. Then the scFv synthesis was induced by adding isopropyl β-D-thiogalactoside (IPTG) to a final concentration of 1 mM and the incubation was continued for another 4 h. The periplasmic proteins were extracted by osmotic shock [26]. Borate buffer was added to the periplasmic fraction to a final concentration of 0.2 M sodium borate, pH 8.0, and 0.16 M NaCl. The scFvs were purified by affinity chromatography with activated protein A Sepharose (Pharmacia) to which the anti c-myc tag 9E10 monoclonal antibody [25] was covalently attached.

Cloning in plant vectors and tobacco transformation

To generate constructs suitable for cloning in plant vectors without the signal sequence the pNEM-scFv and pNEM-scFv-K vectors were digested with *Nco*I and the ends were filled in with Klenow. After digestion with *Hin*cII at the *Sal*I site the fragments were purified and blunt-end-ligated resulting in the vectors pNEM-scFv-C and pNEM-scFv-CK, respectively. Thus, the *Nco*I site was restored providing the ATG start codon in the proper reading frame. Furthermore, the ATG start codon was placed at position −3 of the mature scFv sequence. The constructs lacking the KDEL sequence were cloned as *Sal*I/*Sma*I (pNEM-scFv) or *Nco*I/*Sma*I (pNEM-scFv-C) fragments into the *Nco*I/*Sma*I digested plant vector pCPO33T. For construction of the scFv-S the *Nco*I/*Sal*I signal sequence fragment was also included in the ligation mixture. The resulting vectors, pCPO-scFv-S and pCPO-scFv-C, had the single chain construct in frame with the c-myc tag sequence. The scFv-K and scFv-CK constructs were cloned as *Sal*I/*Bcl*I (pNEM-scFv-K) and *Nco*I/*Bcl*I (pNEM-scFv-CK) fragments and transferred to the *Sal*I/*Bgl*II-digested pCPO35 and *Nco*I/*Bgl*II-digested pCPO33, respectively. The resulting vectors were designated as pCPO-scFv-SK and pCPO-scFv-CK. All vector-scFv junctions were verified by sequencing.

Tobacco transformation was conducted according to van Engelen *et al.* [37].

Protoplasts

Transient expression assays in tobacco (*N. tabacum* cv. Samsun NN) leaf protoplasts were performed according to the polyethylene glycol procedure as described by Denecke *et al.* [7]. The same protoplasts isolation and culture method was employed to study secretion and retention in transgenic plants. Protoplasts and culture medium were separated by centrifugation and analysed by western blotting experiments and ELISA. For western analysis the proteins present in the culture medium were precipitated with 3 volumes of ethanol. Both protein pellet and protoplasts were dissolved in SDS-PAGE sample buffer (see: protein extraction and analysis). For ELISA the culture medium was diluted 1:1 with PBS, 0.1% Tween, 1% skimmed milk powder and 1 mM 4-(2-aminoethyl)-benzenesulphonyl fluoride hydrochloride (Pefabloc SC, Boehringer) and the protoplasts were lysed in the same buffer. All samples were further treated as described in protein extraction and analysis.

RNA extraction and analysis

For extracting total RNA from plant tissues the guanidine hydrochloride procedure of Logemann *et al.* [23] was used. The RNA concentration was measured spectrophotometrically and northern analysis was carried out according to Sambrook *et al.* [30].

Briefly, 9 μg RNA was separated on a 1.2% (w/v) agarose (Pharmacia) formaldehyde gel. As size marker 1 ng denatured 21C5 scFv DNA and 1 μg of the 0.16–1.77 kb RNA ladder (Life Technologies) were used. After electrophoresis the gel was incubated twice for 15 min in DEPC-treated double distilled water and the RNA was transferred to a Hybond-N + membrane (Amersham) by vacuum blotting, using 20 × SSC as transfer buffer, and cross-linked to the membrane under UV light at 1.5 J/cm^2. The blot was hybridized with [α-^{32}P]dATP-labeled probes at 65 °C for 48 h and further treated as described by Church and Gilbert [6]. The stringency of the final washing was 0.2 × SSC at 65 °C. The blot was first hybridized with a labeled scFv DNA fragment, isolated as *Sal*I-*Sma*I fragment from pNem-scFv. To establish the differences in the amount of total RNA the blot was hybridized with a ribosomal probe. To estimate the molecular sizes the blot was hybridized to labeled cDNA of the RNA ladder. All probes were obtained by random prime labeling [10].

Protein extraction and analysis

Proteins were extracted by grinding tobacco leaves in liquid nitrogen to a fine powder. The powder was transferred to an eppendorf tube and mixed 1:1 (w/v) with SDS-PAGE sample buffer, containing 61 mM Tris-HCl pH 6.8, 2% (w/v) SDS, 12.5% (w/v) glycerol, 1 mM Pefabloc SC (Boehringer). Insoluble plant material was pelleted by centrifugation for 5 min at 13000 rpm. The protein concentration in the supernatant was determined using the BCA method [34]. To the supernatant DTT and bromophenolblue were added to final concentrations of 40 mM and 0.008% (w/v), respectively, and the samples were boiled at 100 °C for 5 min. For non-reducing gel electrophoresis DTT was omitted during sample preparation. Thirty μg of total protein was loaded on a 13% SDS-polyacrylamide gel [22] (BioRad mini protean system). After electrophoresis the proteins were transferred to a PVDF membrane (Millipore) by electroblotting. For immunodetection the membranes were incubated with 1:1000 diluted 9E10 monoclonal antibody, followed by a 1:5000 diluted rat-anti-mouse alkaline phosphatase conjugate (Jackson Immuno Research). Alternatively, a rabbit polyclonal anti-21C5 serum, precleared from antibodies reacting to the constant domains, was used in conjunction with a 1:2500 diluted goat-anti-rabbit alkaline phosphate conjugate (Jackson Immuno Research). The blots were stained in 0.1 M ethanolamine-HCl pH 9.6, supplemented with 4 mM $MgCl_2$, 5-bromo-4-chloro-3-indolyl phosphate (0.06 mg/ml) and nitroblue tetrazolium (0.1 mg/ml). The relative molecular weights of the proteins were estimated with pre-stained low-range molecular weight markers (BioRad).

Purification of native scFv 21C5 antibody from plant extracts was carried out by polytron homogenization of 4 g tobacco leaves in 4 ml 0.2 M sodium borate pH 8.0, containing 0.16 M NaCl and 1 mM Pefabloc SC (Boehringer), in the presence of 200 mg insoluble polyvinylpyrrolidone (Serva). The soluble protein fraction was isolated by centrifugation and filtered through a 0.45 μm filter (Millipore). The scFvs were purified by affinity chromatography with the 9E10 monoclonal antibody coupled to activated protein A Sepharose (Pharmacia) as described previously.

For use in ELISA assays the proteins were extracted by grinding 0.2–0.4 g tobacco leaves in liquid nitrogen to a fine powder. The powder was transferred to an Eppendorf tube and mixed 1:2 (w/v) with PBS-0.1% (v/v) Tween (PBST) and 1 mM Pefabloc SC (Boehringer), and incubated on ice for 5 min. Insoluble material was removed by centrifugation at 13000 × *g*. The supernatant was stored at −80 °C until further use.

The cutinase binding activity of the crude supernatant or purified scFv was determined by

ELISA. A 96-well plate was coated overnight at 4 °C with 1 μg/ml cutinase in 50 mM sodium carbonate, pH 9.6 (100 μl/well). After blocking for 30 min with 200 μl PBST-5% skimmed milk powder per well the plates were washed and 100 μl protein extract per well was added. The plate was incubated for 2 h. To determine the antigen-binding capacity of the scFv antibody preparations, the wells were subsequently washed with PBST, eluted with SDS-PAGE sample buffer, and analysed by immunoblotting under non reducing conditions. Alternatively, for quantitative ELISA, after washing with PBST each well was incubated for another 2 h with 100 μl anti c-myc tag antibody 9E10 (1 ng/μl) in PBST-1% skimmed milk powder. Then, after washing three times with PBST, the wells were incubated for 1 h with alkaline phosphatase conjugated rat-anti-mouse antibody (Jackson Immuno Research), diluted 1:5000 in PBST-1% skimmed milk powder. Finally the wells were washed five times with PBST and 100 μl substrate (0.75 mg/ml p-nitrophenylphosphate in 1 M diethanolamine, pH 9.8) was added and the OD_{405} was monitored. All incubations were carried out at 37 °C.

Results

Construction of the scFv expression cassettes

An scFv gene was constructed containing the variable domains of the 21C5 antibody heavy- (V_H) and light-chain (V_L) genes [37] in the 5′-V_L-linker-V_H-3′ orientation. The end of the V_H region was fused to the *c-myc* tag coding sequence for detection and purification purposes. To enable translocation of the 21C5 scFv to the lumen of the ER it was preceded by a murine κ light-chain signal peptide (scFv-S; Fig. 2A). This sig-

Individual points represent mean values of triplicate trials with standard deviations (error bars).

nal peptide has shown previously to export full-size antibodies efficiently to the plant apoplast [37]. To retain the scFv-S antibody in the ER a C-terminal ER retention signal KDEL was added (scFv-SK; Fig. 2A). In addition two cytosolic versions of the 21C5 scFv (scFv-C and scFv-CK; Fig. 2A) were constructed, which both lacked the ER translocation signal.

To determine if the presence of the KDEL retention signal had any effect on either antigen-binding capacity or detection with the anti c-myc tag antibody, the scFv genes, with and without KDEL sequence, were expressed in *E. coli* (Ec-scFv-K and Ec-scFv, respectively; Fig. 2A). Both scFv genes were preceded by the pelB signal peptide. After affinity purification the Ec-scFv and Ec-scFv-K antibodies showed similar binding properties to the cutinase antigen in an ELISA assay (Fig. 2B). Western blotting followed by immunodetection using the anti c-myc tag antibody revealed proteins of 31 kDa (Fig. 3). Apparently, addition of the KDEL retention signal had no effect on the binding properties of the anti c-myc tag antibody 9E10.

Expression of scFv antibodies in transgenic tobacco leaves

The scFv cassettes were introduced into tobacco by *Agrobacterium* mediated transformation. As a control, transformation also was conducted using the empty vector pCPO33T. Independent kanamycin-resistant transformants were screened by immunoblotting of total protein extracts from leaves. All 43 plants containing the scFv-S constructs showed poor expression. By comparison of the staining intensity on western blot of the plant produced scFv protein with known amounts of bacterially produced scFv, it was estimated that the maximum expression level reached was 0.01% of total protein. No scFv protein was detected in 23 plants containing the scFv-C construct. However, 9 out of 15 scFv-CK transformants showed scFv antibody expression with a maximum level of 0.2% (Fig. 3). Of the 15 scFv-SK transformants 13 were expressing scFv

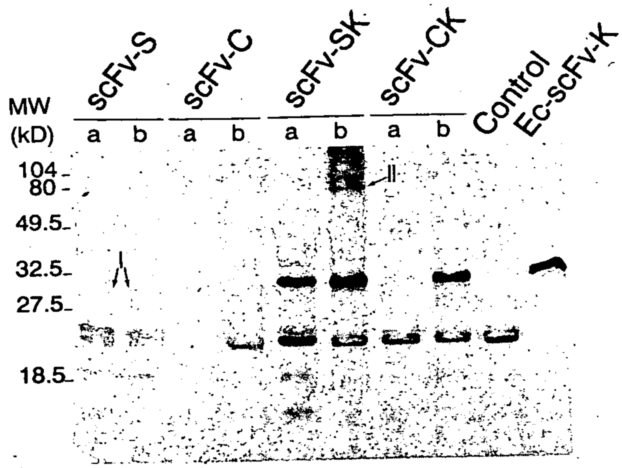

Fig. 3. Western blot analysis of leaf tissue from two independent tobacco transformants (a and b) containing the scFv-S, scFv-C, scFv-SK and scFv-CK cassettes. The lanes marked 'Control' are from a transgenic tobacco plant transformed with the vector pCPO33T. The scFv antibodies were detected using the anti c-myc antibody (9E10). The arrows marked 'I' indicate the scFv-S antibody and the arrow marked 'II' indicates the 65 kDa protein band.

protein, the highest expression level being 1.0% (Fig. 3).

In plants expressing the scFv-SK protein an additional minor product of ca. 65 kDa was detected. To gain more insight into the nature of this 65 kDa band, protein samples were prepared from leaves and analysed under non-reducing conditions. Western blotting showed that under these circumstances the fraction of the 65 kDa protein increased considerably for both scFv-SK and scFv-CK protein preparations (Fig. 4A). This could indicate that in plant cells the cysteine residue present in the linker peptide (Fig. 2A) may have been involved in dimer formation. To determine if both scFv protein and the presumed scFv-dimer had antigen-binding capabilities, purified scFv-CK and scFv-SK antibodies were incubated with immobilized cutinase and analysed after elution under non-reducing conditions (Fig. 4B). Purified bacterially expressed Ec-scFv-K was used as a control. Western blotting of the eluents showed that not only scFv-CK and scFv-SK monomers, but also the 65 kDa proteins bound specifically to the cutinase antigen.

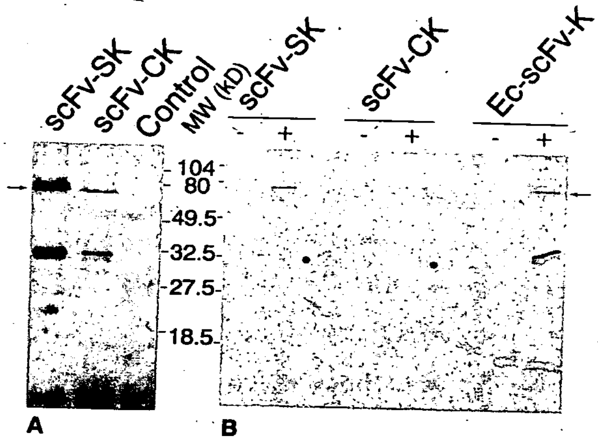

Fig. 4. A. Western blot of proteins from scFv-SK and scFv-CK transgenic tobacco after non-reducing electrophoresis. The scFv antibodies were detected using the anti c-myc antibody (9E10). Arrow indicates the 65 kDa protein band. B. Binding of scFv antibodies to cutinase. Immunoblot of proteins eluted from wells coated with (+) or without (−) cutinase after incubation with scFv-SK and scFv-CK antibodies purified from plants and the Ec-scFv-K antibody purified from *E. coli*. The antibodies were detected with the anti-c-myc antibody (9E10). Asterisk and arrow indicate the scFv antibodies and 65 kDa protein bands, respectively.

Accumulation of scFv mRNA and protein in transgenic tobacco leaves

Since the KDEL retention signal is thought to function only in the secretory pathway the difference in expression level between the scFv-C and scFv-CK was a surprise. Therefore, we investigated whether the differences in protein accumulation between the various constructs could be explained by differences in the steady state mRNA levels. For a number of plants both total RNA and protein was isolated from the same leaf and analysed (Figs. 3 and 5).

Northern blot analysis showed that the scFv transgenic plants accumulated scFv mRNA of the expected size of 1000–1200 bases, albeit in different quantities (Fig. 5A). In addition, a much less abundant mRNA of 1400 bases was detected. The origin of this mRNA is not clear. It was not detected in control plants and therefore may be a read-through product of the scFv messenger

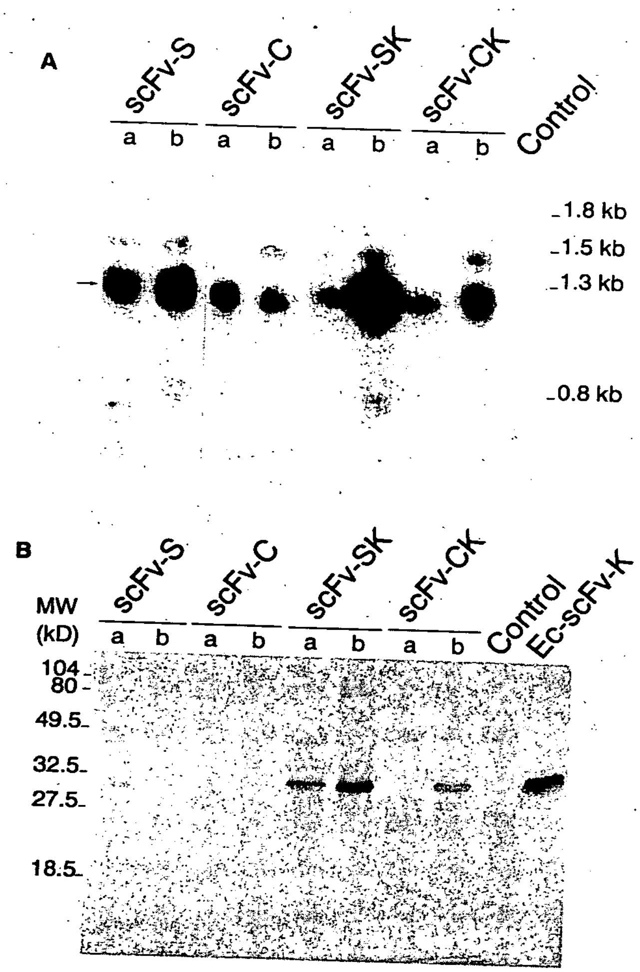

Fig. 5. RNA and protein analysis of leaf tissue from the same independent tobacco transformants as depicted in Fig. 3. A. RNA blot containing total RNA hybridized with a specific scFv probe. Arrow indicates position of scFv transcripts. B. ScFv antibodies detected on western blot using the polyclonal rabbit antiserum against the 21C5 antibody.

RNA. The difference in protein expression level between the different scFv genes could not be explained by various levels of scFv mRNA. The scFv-C mRNA level (Fig. 5A, lane a) was comparable with the scFv-CK mRNA level (Fig. 5A, lane b) but no scFv-C protein was present whereas scFv-CK protein was detected (Figs. 3 and 5B, lanes a and b). Furthermore, a low scFv-SK mRNA level (Fig. 5A, lane a) resulted in a higher scFv protein accumulation than the

relative high scFv-S mRNA level (Fig. 5A, lanes a and b).

To exclude the possibility that the c-myc tag had been removed by plant proteases, thereby affecting our detection procedure, we used both anti-tag antibodies (Fig. 3) and an anti-21C5-Fv rabbit polyclonal antiserum (Fig. 5B) for scFv detection in a number of transgenic plants. Essentially the same results were obtained, indicating that the presence of the complete scFv antibody correlated with the presence of the tag.

The addition of the KDEL retention signal elevated the steady-state levels of the 21C5 scFv antibody, both with and without signal peptide.

Expression of the scFv antibodies in tobacco leaf protoplasts

The four different mature scFv proteins varied slightly in their number of amino acids (Fig. 2A). The calculated sizes of the mature scFv proteins ranged from 30 kDa for the scFv-S to 31 kDa for the scFv-CK. An uncleaved signal peptide would increase the calculated size for the scFv-S and scFv-SK antibodies by 2.5 kDa. On western blot the protein bands showed only minor size differences, the smallest molecule being the scFv-S protein (Fig. 3). This might indicate that the signal peptides of both scFv-S and scFv-SK proteins were recognized and cleaved off during translocation into the ER.

To determine whether the signal peptide and the KDEL retention signal had the predicted effects on scFv protein translocation, transient expression assays were carried out in tobacco protoplasts. Western blot analysis showed differences in the location of the scFv proteins (Fig. 6). As expected, the scFv-S protein was secreted into the incubation medium indicating that the signal peptide was indeed functional. The scFv-SK and scFv-CK proteins were predominantly found inside the protoplasts. The residual presence of scFv-CK and scFv-SK protein in the incubation medium was probably due to cell disruption during the assay, since in a control experiment expressing a β-glucoronidase (GUS) construct

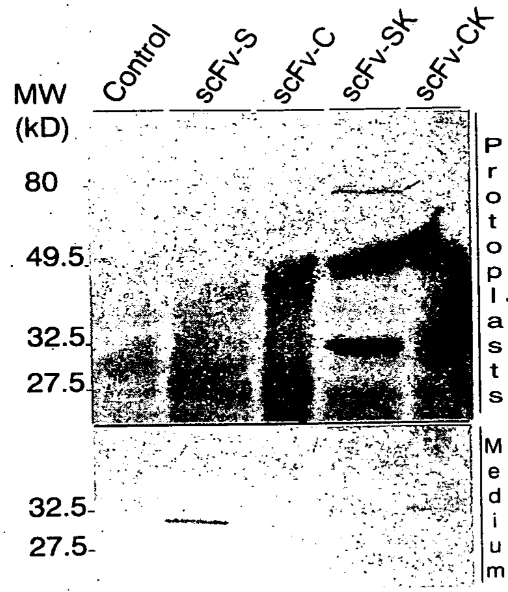

Fig. 6. Western blot analysis of a transient expression assay in tobacco protoplasts transformed with plant vectors containing the scFv-S, scFv-C, scFv-SK and scFv-CK gene cassettes. The 'Control' lane represents the transformation of tobacco protoplasts with the vector pCPO33T. The scFv antibodies present in the cells and incubation medium were detected by the anti c-myc antibody (9E10). Arrow indicates the 65 kDa protein band.

lacking a signal peptide some GUS activity was detected in the medium. From the data obtained with the scFv-SK expression we concluded that the KDEL retention signal was able to retain the scFv-SK antibody inside the protoplasts. This was confirmed by using protoplasts, prepared from the transgenics with a high scFv mRNA level, which showed only intracellular accumulation of the scFv-SK. However, in this case we could not detect the scFv-S antibody, neither in the protoplasts nor in the medium (results not shown).

Discussion

Successful applications for scFv antibodies expressed in plants, including creating resistance against pathogens [36] or altering metabolic pathways (e.g. catalytic antibodies), will to a large

degree depend on the ability to target the scFvs to a particular subcellular compartment and to optimize their expression level. Tavladoraki *et al.* [36] described the successful expression of an scFv antibody directed to the cytosol. Firek *et al.* [11] reported a significant increase in the expression level of an scFv antibody against phytochrome when secreted instead of expressed in the cytosol [27]. They suggested that this difference in expression levels was not the result of a difference in subcellular location but was caused by a destabilizing effect of the phytochrome on the cytosolic scFv [11].

Since no further data on the expression of scFv antibodies in different subcellular compartments of plant cells were available we decided to explore the possibilities of intracellular targeting of scFv antibodies and assess the effect on stability and accumulation. To improve intracellular stability we targeted an scFv antibody away from the cytosol to the potentially more favourable environment of the endoplasmic reticulum (ER) by adding a signal peptide and the tetrapeptide KDEL [8, 16, 40] (scFv-SK). For comparison, a secretory version (scFv-S) of this molecule was used, as well as two cytosolic counterparts, one with and one without the KDEL retention signal (scFv-CK and scFv-C, respectively). The expression level and localization of this scFv-SK antibody were compared with those of the scFv-C, scFv-CK and scFv-S antibodies.

Of the tobacco transformants expressing the scFv-SK cassette, 85% showed a high accumulation of the protein in leaves. In some plants the scFv protein comprised up to 1% of the total soluble protein. Protoplasts prepared from these transgenic plants showed total retention of scFv-SK in the cells. This was confirmed by transient expression assays in tobacco protoplasts. The ScFv-SK antibody was retained intracellularly while a large proportion of the scFv-S antibody was secreted into the culture medium. These results indicated that the signal peptide was functional. Furthermore, they showed that the KDEL retention signal was probably well exposed, recognized by a salvage receptor [35, 38], thereby enabling the scFv antibody to be retained in the ER. When compared with the plants expressing the secreted scFv (scFv-S) the retention in the ER resulted in a 100-fold increase in the amount of detectable scFv antibody. These high accumulation levels cannot be explained by differences in the mRNA levels. It therefore seems that the high level of scFv antibody accumulation is due to its strict localization in the ER and consequently is protected from proteolytic activity further down the secretory pathway, either intra- or extracellularly. Similar results have been obtained with the vacuolar protein vicilin, which also accumulated to a much higher level when retained in the ER [40].

Most striking were the differences in expression levels obtained with the scFv-C and scFv-CK constructs. No transgenic tobacco plants could be found with detectable levels of scFv-C antibody. In contrast to this finding, among the scFv-CK transformants 60% of the plants showed detectable antibody levels. In one plant the scFv-CK protein level reached 0.2% of total soluble protein, which is comparable with previously reported cytosolic expression levels [27, 36]. This difference in expression between the two constructs (scFv-C and scFv-CK) was also found in the transient expression assay. The steady state levels of scFv mRNA indicated that the difference in protein accumulation most likely depended on differences in stability of the protein. This phenomenon is not unique for the anti-cutinase scFv, since we have recently obtained similar results with another scFv antibody (unpublished results).

Presently we can only speculate on the factors which cause these KDEL correlated differences in expression in plants. Assuming that both scFv-C and scFv-CK antibodies are located in the cytosol, it might be possible that the C-terminal extension of the scFv-CK antibody, which is in fact six amino acids long (DIKDEL), protects the scFv from C-terminal degradation by exo-proteinases. This then would suggest that particular exo-proteinases are involved in the breakdown of scFvs. Alternatively, the DIKDEL sequence may indirectly protect the scFv from proteolytic attack via a KDEL mediated interac-

tion with the cytosolic side of the ER salvage receptor [35].

Another explanation for the observed differences could be that expression levels of the scFv are correlated to a different subcellular location. It has been well documented that the expression of normally secreted proteins, particularly those with disulphide bridges, in the cytosol of plant cells is very low [4, 12, 33]. It is therefore not surprising that the scFv-C transformants failed to produce detectable amounts of scFv antibodies. Protein analysis using the algorithm for predicting signal peptidase cleavage sites [39] within the GCG Wisconsin program revealed that both mature scFv-C and scFv-CK proteins did not contain a signal peptide-like sequence in the amino-terminal region. Possibly, the KDEL containing scFvs, even when no signal peptides are added, are directed away from the cytosol to a more favourable location, presumably the ER. The presence of substantial amounts of the 65 kDa protein in the scFv-CK transgenic plants along with its functionality might indicate an ER location. Noteworthy in this respect is the recent suggestion that scFv antibodies targeted to the cytosol of animal cells were actually 'mistranslocated' to the ER [20]. In addition, alternative pathways for secretory proteins, lacking signal peptides, have been put forward [24].

The very low expression from the scFv-S construct in transgenic plants and transgenic protoplasts contrasts with the result obtained in transient expression experiments where we could detect the scFv-S extracellularly. Possibly the protoplasts used for the transient assay were physiologically different from the transgenic scFv-S protoplasts and produced less proteases into the incubation medium. Firek *et al.* [11] reported high expression levels in plants when an anti-phytochrome scFv antibody was being secreted. This difference in stability between different scFv antibodies is not clear but may depend on the amino acid constitution in the variable domains of the scFv antibodies or the linkerpeptide.

Efficient expression of scFv antibodies in different subcellular sites seems feasible. However, it should be kept in mind that successful expression of functional scFvs in the cytosol may only be found under certain conditions, like an scFv amino acid sequence which remains relatively stable [36] or at least can be stabilized by the presence of the antigen [1, 11]. The C-terminal addition of the retention sequence KDEL as a contributing factor for scFv stabilization opens additional opportunities for expressing scFv antibodies in plants.

Acknowledgements

We would like to thank Dr Jesús Salinas for providing the anti-cutinase hybridoma cell line and Jan de Boer for critical reading of the manuscript and helpful discussion. This work was financially supported by grants from the Netherlands Technology Foundation (STW), coordinated through the Foundation for Life Sciences (SLW), and the European Commission (BIO2-CT92-0239).

YIELDS OF ACPs RETAINED BY THE ANTI-*Escherichia coli* ACP IMMUNOAFFINITY COLUMN[3]

Source of ACP purified by affinity chromatography	Protein (μg)[11]	Units of ACP activity[a]	ACP-dependent fatty acid synthase activity[b]
E. coli	160	203	+
Euglena gracilis strain Z	151	162	+
Euglena gracilis var. *bacillaris*	168	NM[c]	+

[a] One unit of ACP is 1 nmol of $^{14}C_2$ exchanged per 15 min in the malonyl-CoA–CO_2 exchange reaction. The specific activities of the ACPs purified are lower than those reported for freshly reduced, desalted ACP. This is probably due to the absence of a thiol reagent during the chromatographic procedures and to the high salt concentration of the eluents.

[b] ACP is a substrate for the ACP-dependent fatty acid synthase from *Euglena gracilis*. There is no fatty acid biosynthesis in the absence of ACP; therefore, fatty acid biosynthesis is a sensitive indication of the presence of functional ACP.

[c] NM, not measured.

phate, pH 6.2, 0.5 *M* NaCl, until the absorbance (280 nm) of the effluent is zero. Finally, specifically bound ACP is removed by elution with 0.2 *M* glycine, pH 2.8, 0.5 *M* NaCl. After elution of antigen, the immunoadsorbent is equilibrated and stored in 0.01 *M* potassium phosphate, pH 6.2, 0.1 *M* NaCl. It should be washed with several column volumes of the same mixture every 2 weeks.

Properties of the Protein Retained on the Immunoaffinity Column

The elution profiles of *E. coli*, *E. gracilis* strain Z and variety *bacillaris* ACPs from the immunoaffinity column are shown in Fig. 3. In each case, upon application of a crude preparation to the column, protein is specifically retained and later released under acidic conditions. When an excess of pure *E. coli* ACP is processed through the column, a similar result is obtained. The yield achieved in the immunoaffinity chromatography step is a function of the binding capacity of the immunoadsorbent. The yields are identical from one column run to the next (Table) regardless of the excessive amount and stage of purity of the ACP applied to the column. Discontinuous electrophoresis, in 14% acrylamide gels, of the material applied to the affinity column and of the selectively retained protein demonstrates the extent of purification achieved by the single step (Fig. 4).

The material retained from the crude *E. coli* ACP preparation shows a single major band at R_f 0.85 (Fig. 4B), identical to *E. coli* ACP purified according to Majerus *et al.*[4] (Fig. 4C). The single peak retained from E.

gracilis strain Z 70–95% saturation ammonium sulfate fraction exhibits a major band at R_f 0.30, a lesser band at R_f 0.35, and one or two other very faint bands (Fig. 4D). Since the immunoaffinity chromatography is done in the absence of thiol reagents, it is possible that some of the ACP is present as disulfide bridge-linked dimer.[2] The elution pattern of *E. gracilis* var. *bacillaris* ACP from the immunoaffinity column is biphasic (Fig. 3C), but electrophoresis of material in each peak shows a single protein band at R_f 0.39 (Fig. 4G,H). In all cases, upon neutralization and concentration, the retained protein is biologically active in the ACP assays (Table).[11]

The small-scale purifications described here illustrate the potential usefulness of immunoaffinity chromatography in obtaining ACPs from diverse sources. Under the conditions described, stable and reproducible results are obtained through more then 25 runs on a single column.

[23] Acyl-Acyl Carrier Protein Thioesterase from Safflower

By TOM MCKEON and PAUL K. STUMPF

The acyl-ACP[1] thioesterase catalyzes the hydrolysis of acyl-ACP to free fatty acid and ACP-SH.

$$\text{Acyl-S-ACP} + H_2O \rightarrow \text{acyl-OH} + \text{ACP-SH}$$

The thioesterase is of interest because it terminates the set of biosynthetic reactions that take place on ACP, a water-soluble and lipid-insoluble acyl carrier. Further metabolism of fatty acids appears to occur in membrane systems. Thus, acyl-ACP thioesterase may play an important role in regulating the fatty acid composition of plant tissue.[2]

[1] The abbreviations are ACP, acyl carrier protein; BSA, bovine serum albumin.

[2] W. E. Shine, M. Mancha, and P. K. Stumpf, *Arch. Biochem. Biophys.* **172,** 110 (1976).

Assay Method

Principle. The acyl-ACP thioesterase assay involves the measurement of labeled fatty acid released from labeled acyl-ACP. The free fatty acids are extracted into petroleum ether and counted in a liquid scintillation counter.

Reagents

- Glycine, 0.20 *M*, pH 9.0
- Bovine serum albumin, 10 mg/ml in water
- [^{14}C]Stearoyl-ACP, 10 μM in 0.02 *M* potassium phosphate, pH 6.8 (synthesis described in this volume[3]
- Acetic acid, 1 *M*, in isopropanol with 5 mg/ml each of palmitic and stearic acid
- Petroleum ether, reagent grade, saturated with isopropanol–water, 1 : 1 (v/v)

Procedure. The reaction mixture in a 13 × 100 mm screw-cap tube contains 100 μl of glycine buffer, 70 μl of water, 10 μl of BSA and 10 μl of thioesterase preparation appropriately diluted. The reaction is started by the addition of 10 μl of [^{14}C]stearoyl-ACP, and the reaction is stopped after 10 min at room temperature (20–23°) by the addition of 0.2 ml of the 1 *M* acetic acid reagent. After 10 min, the free fatty acids are extracted with two 2-ml portions of the petroleum ether and the extract is counted.

The assay is linear with respect to time and enzyme concentration up to 40% hydrolysis of substrate.[4] One unit of activity is equal to a rate of hydrolysis of 1 μmol per minute per milligram of protein.

Purification

Acetone Powder Extract. This material is obtained from acetone powder of safflower by the method described for stearoyl-ACP desaturase.[3]

Acid Precipitate. The acetone powder extract is cooled on ice and acidified to pH 5.2 with glacial acetic acid. After 1 hr, the precipitate is centrifuged at 10,000 *g* for 10 min, and the supernatant is adjusted to pH 4.3 with acetic acid. After 1 hr, the precipitate is pelleted and resuspended in one-half the starting volume of 0.02 *M* potassium phosphate buffer, pH 6.8. Insoluble debris is centrifuged out, and the supernatant retains 60% to 80% of the acyl-ACP thioesterase activity (see the table) and less than 5% of the stearoyl-ACP desaturase activity.[4]

ACP-Sepharose 4-B column. This column is run exactly as described

[3] T. McKeon and P. K. Stumpf, this volume [34].

[4] T. McKeon, unpublished data, 1979.

PURIFICATION OF ACYL-ACP THIOESTERASE

Fraction	Total protein[a] (mg)	Total activity (mU)	Specific activity (mU/mg)	Yield (%)	Purification (fold)
Acetone powder extract	400	86	0.22	—	—
Acid precipitate	57	64	1.12	74	5
ACP-Sepharose 4B	.13	23	170	27	770

[a] Protein was determined by the method of O. H. Lowry, N. J. Rosebrough, A. L. Farr, and R. J. Randall, *J. Biol. Chem.* **193,** 265 (1951), using bovine serum albumin as the standard.

for the purification of stearoyl-ACP desaturase. The thioesterase elutes with the 0.30 *M* phosphate wash, with the early fractions containing proportionally more thioesterase and the later fractions more of the desaturase.[4]

Purity. As seen in the table, the acyl-ACP thioesterase is purified 770-fold by this procedure. The stearoyl-ACP desaturase is present as approximately 5% of the bulk protein in the purified preparations of the thioesterase.[4]

Properties

Specificity. Acyl-ACP thioesterase from safflower has a strong preference for oleoyl-ACP as substrate. The preference for substrates under routine assay conditions is oleoyl-ACP > stearoyl-ACP > palmitoyl-ACP with relative rates of 10 : 2 : 1, respectively. The rates of hydrolysis of oleoyl-CoA and stearoyl-CoA are less than 2% of the rate of hydrolysis of the corresponding acyl-ACP.[4]

Stability. Preparations purified through the ACP-Sepharose 4B column step are stable for 3 weeks at 4° when maintained in 1 m*M* DTT.[4]

pH Activity Profile. The thioesterase is half-maximally active at pH 8.5 and pH 10.0 with optimum activity at pH 9.5. The thioesterase has less than 2% maximal activity at pH 6.5 and below, where the stearoyl-ACP desaturase is maximally active.[4]

Preface

The interactions of fungi with mankind are both beneficial and harmful and are deeply rooted in the history of human society and agriculture. Over the centuries man has sought to manipulate the growth of fungi to his advantage; the methods used though largely empirical have often been highly successful. Since the initial development of recombinant DNA technology in bacteria in the early 1970s, biology has been undergoing a revolution which is spreading to all organisms, including fungi. This revolution is marked by the emergence of a new discipline, molecular biology, at the interface between biochemistry and genetics. The approach and techniques of molecular biology enable us to ask and answer fundamental questions about many aspects of fungal biology, and open the way to the directed manipulation of fungal metabolism.

This book arises from a symposium on 'Fungal Molecular Biology' held by the British Mycological Society at the University of Nottingham in April 1990. Altogether, there were 29 main papers presented at the symposium, covering a broad range of both fundamental and applied aspects of fungal molecular biology. In considering a book based on the meeting it seemed desirable, given the inevitable restrictions on space and cost, to focus on one or two areas. The editors decided to highlight the rapid development of gene transfer and cloning techniques in fungi and the ways in which these are being exploited in species of economic importance either in biotechnology or as plant pathogens. The 11 contributions in this volume were selected on that basis.

The relevant methodologies for gene manipulations in fungi are described in the first three chapters. In chapter 1 (Van den Hondel & Punt) the development of suitable vectors and gene transfer systems for filamentous fungi discussed and the wide applicability of these techniques to all fungi is clearly established. One point that emerges is that although a basis of classical genetics is useful, it is not essential. A central feature of this new approach to genetic manipulation is the cloning of genes; several strategies are available in filamentous fungi and the most applicable in each situation can be readily identified (Chapter 2, Turner). To date, the technology for introducing vectors into fungal cells has been restricted

uptake into protoplasts. Workers manipulating plant and animal cells have explored more 'dramatic' procedures as described by Watts & Stacey (Chapter 3).

Not surprisingly, progress in yeast molecular biology has been even more rapid than that with filamentous fungi. Several contributions concerning yeast research were included in the symposium to provide a point of reference for possible future developments with the filamentous fungi. Advances with *Saccharomyces cerevisiae* stem, in part, from its importance in brewing, where several opportunities for exploitation of recombinant strains exist (Chapter 8, Hinchliffe), but mainly from previously established fundamental knowledge of biochemistry, cell biology and genetics in this organism. A clear example of building on the latter is the use of *Saccharomyces* as a host for the expression of heterologous proteins (Chapter 4, Ogden). Despite the fact that this fungus secretes only a limited range of proteins naturally, it can be engineered genetically to secrete significant amounts of recombinant proteins. The success with *Saccharomyces* prompted interest in several other yeasts including the methylotrophic species and several systems are now operational (Chapter 7, Veale & Sudbery; Chapter 10, Strasser *et al.*).

Industrially, the filamentous fungi are best known as sources of antibiotics, organic acids and enzymes. Several of the genes encoding biosynthetic enzymes for β-lactam synthesis have been cloned and manipulated; the advances made in this area in *Cephalosporium* (*Acremonium*) are considered by Skatrud *et al.* (Chapter 9). *Trichoderma* species are used commercially as the producers of a range of hydrolytic enzymes which are secreted into the growth medium. The cellulase system has been investigated using molecular genetic techniques and this has led not only to improvements in cellulase production, but also to the exploitation of this fungus as a host for the expression of heterologous proteins (Chapter 5, Penttilä *et al.*). The Aspergilli are of particular importance in fungal molecular biology as they contain both model experimental and industrially important species. Several of these species are the subject of intense study aimed at developing them as hosts for the commercial production of mammalian proteins (Chapter 6, Davies).

The detrimental economic effects of fungi as agents of plant disease are of even greater importance than the beneficial role of fungi in biotechnology. Most phytopathogenic fungi are not amenable to study by the classical methods of genetics and biochemistry and, as a result, the basic mechanism of fungal pathogen-plant host interactions are poorly understood. However, the approach and techniques of molecular genetics bypass many of these difficulties and are transforming knowledge of all aspects of the biology of these fungi. Clearly there is along way to go before we under-

stand the molecular basis of fungal pathogenicity, but sound foundations are being laid as described in the final chapter (Chapter 11, Oliver *et al.*).

The editors of this volume are grateful to the British Mycological Society for providing the means to organise such a timely and interesting symposium and for supporting the publication of this volume. Generous donations towards the costs of the symposium from Bicon Biochemicals, Cambridge University Press, Glaxo Group Research, Pfizer, SmithKline Beecham and Xenova are gratefully acknowledged. We wish to thank all those who contributed to the meeting and, in particular, the authors of the chapters in this volume for their cooperation in preparing the manuscripts for this book in as short a time as possible. Finally, special thanks go to David Moore and Page Design for their help, guidance and great efficiency in producing the book.

Chapter 1

Gene transfer systems and vector development for filamentous fungi

Cees A. M. J. J. van den Hondel & Peter J. Punt

Filamentous fungi have a number of properties which make them important both scientifically and economically. The economic importance can be illustrated by the large variety of products that are made by filamentous fungi, such as organic acids (e.g. citric acid), antibiotics (e.g. penicillin and cephalosporin) and numerous industrial enzymes (e.g. glucoamylase). Filamentous fungi are also used as food (mushrooms), food additives (e.g. the meat extender 'Quorn') and condiments (e.g. soy sauce). A severe, negative economic influence of filamentous fungi is their detrimental effect on crop yield. Plant pathogenic fungi cause annual crop losses of billions of pounds. In addition to their economic importance, filamentous fungi have interesting biological properties such as a complex life cycle, cell differentiation, highly regulated metabolic pathways and efficient secretion of proteins which make them attractive as a model for basic biological research of eukaryotic organisms.

In the pre-recombinant DNA period, physiological, biochemical and genetic studies were mainly carried out with *Neurospora crassa* and *Aspergillus nidulans*. Their haploid genomes, rapid life cycles, simple nutrient requirements and well developed genetic systems made them attractive model systems. Hence, it stands to reason that after the introduction of recombinant DNA techniques, systems for molecular genetic analysis were first developed in these intensively studied filamentous fungi. Thereafter, similar molecular techniques have been extended to less amenable species.

A prerequisite for molecular genetic research in filamentous fungi is the availability of a gene transfer system comprising a vector containing a selectable marker and a transformation procedure for introduction of the vector into the fungus. The specific properties of different types of selection markers can be used to design vectors for specific genetic manipulation strategies necessary for molecular genetic studies.

Recently, several excellent reviews have been published about transformation and genetic engineering of filamentous fungi (Fincham, 1989; Timberlake & Marshall, 1989; Goosen, Bos & Van den Broek, 1990).

of the gene transfer systems developed. Special attention will be given to some applications of these systems for genetic manipulation in *Aspergillus*.

Gene transfer systems

For genetic manipulation of filamentous fungi a gene transfer system is required that permits introduction of exogenous DNA and selection of those cells that have incorporated this DNA. This selection can be achieved by covalently linking the DNA to a vector which contains a selection marker. Both transformation frequency and type of transformant can be manipulated by using different types of vector.

Transformation procedure

The procedure to obtain DNA-mediated transformed fungal cells comprises the following steps:

- preparation of cells (protoplasts) which are competent to take up (vector) DNA
- treatment of these cells with the DNA
- regeneration of colony forming units
- selection/detection of those cells that have stably incorporated DNA.

A summary of the transformation systems used for filamentous fungi is given in Table 1.1.

Most frequently, protoplasts are used for the introduction of exogenous DNA. These protoplasts are obtained by incubation of mycelium or spores with cell wall-degrading enzymes in the presence of a compound that stabilizes the protoplasts (for an extensive overview of the different procedures and enzymes used, see Peberdy (1989)). Recently, transfor-

mation through electroporation of protoplasts was described (for references, see Table 1.1). Compared to the generally used $CaCl_2$/PEG method, no significant improvement of transformation frequency was observed.

A few reports describe the use of intact cells for transformation. Both incubation of cells with lithium acetate and particle bombardment (chapter 3) have been successfully used for the transformation of filamentous fungi (for references, see Table 1.1). These methods have the obvious advantage that the sometimes laborious protoplast preparation steps can be omitted.

Selection markers

Three types of selectable marker are used for selection of transformed cells: (a) a gene coding for a suppressor tRNA, (b) auxotrophic markers and (c) dominant selectable markers.

To date there is only one example of a suppressor tRNA gene (*su*-8, presumably a mutant tRNA gene) used as selection marker (Brygoo & Debuchy, 1985). Although this type of marker potentially can be used in each fungal strain which contains a suppressible chain termination mutation, no additional reports of the application of suppressor tRNA genes as selection marker have been published.

Auxotrophic markers are the most commonly used method for selection of transformants. Obviously, a prerequisite for their successful use is the presence of the appropriate mutation in the fungus. In Table 1.2 an overview is given of the auxotrophic markers which have been used. As can be seen from this Table, both homologous and heterologous markers can be used for transformation of fungi.

Some of the markers used (e.g. *pyrG*, *niaD* and *trpC*) have proved to be very useful, since they are functional in several species (Table 1.2). Furthermore, both *pyrG* and *niaD* are attractive markers for developing a gene transfer system in genetically poorly characterized fungal species, since the required mutants can be isolated by positive selection. In the case of *pyrG* they can be isolated by resistance against 5-fluoro-orotic acid (Van Hartingsveldt *et al.*, 1987; Goosen *et al.*, 1987) and in the case of *niaD* by resistance against chlorate (Unkles *et al.*, 1989). Since it is possible to select both for and against the mutant and wild-type phenotypes, these markers are also particularly useful for genetic manipulation strategies, such as gene-replacement experiments.

One of the obvious disadvantages of auxotrophic markers is the need to isolate a recipient strain with the appropriate mutation. With dominant selectable markers both wild-type and mutant strains can be transformed. A list of dominant markers which are utilized is given in Table 1.3. Several

of these markers are 'broad-host range' markers which can be employed in different fungal species. All but one of these markers are based on drug-resistance. They consist of either mutant fungal genes such as benomyl resistant β-tubulin (*benA*, May *et al.*, 1985), or bacterial antibiotic-resistance genes provided with expression signals of filamentous fungi. The only exception is the acetamidase gene of *A. nidulans* (*amdS*, Kelly & Hynes, 1985), which is a nutritional marker. Transformants containing this gene are able to use acetamide or acrylamide as a sole nitrogen and carbon source. In general, fungi cannot readily use these compounds as such.

An example of a vector containing a bacterial resistance gene as selection marker is shown in Fig. 1.1. In this case the *Streptoalloteichus hindustanus* phleomycin resistance (*ble*) gene was introduced in a fungal expression vector containing the promoter region of the highly expressed *A. nidulans gpdA* gene and the terminator region of the *A. nidulans trpC* gene (Punt *et al.*, 1987). This vector and a similar one, pAN7-1, containing the *Escherichia coli* hygromycin B resistance gene have been used for the

Types of vector

In general, vectors used for transformation experiments comprise *E. coli* plasmid DNA and the appropriate selectable marker. In most fungal species vector DNA becomes integrated into the genome of the host after transformation. Although considerable effort was undertaken to construct autonomously replicating vectors for *A. nidulans* and *Neurospora crassa*, using a strategy similar to that described for *Saccharomyces cerevisiae* (Stinchcomb, Struhl & Davis, 1979), no autonomous replication of the vector could be detected (Ballance & Turner, 1985; Buxton & Radford, 1984; Paietta & Marzluff, 1985; Van Gorcom, unpublished). In one case, however, a DNA sequence (the *A. nidulans ans1* sequence) which considerably enhances the transformation frequency was isolated. Nevertheless, even this vector did not replicate autonomously (Ballance & Turner, 1985).

For some other species, autonomously replicating vectors were successfully constructed by adding into an integration vector autonomously replicating sequences (ARS) (*Ustilago maydis*, Tsukuda *et al.*, 1988), the chromosomal ends of *Tetrahymena thermophila*, (*Podospora anserina*, Perrot, Barreau & Begueret, 1987), or the termini of naturally occurring linear plasmids of *Nectria haematococca* (*Ustilago maydis*, Samac & Leong, 1989).

In contrast to the results obtained for the ascomycetous fungi, *Neurospora* and *Aspergillus*, in zygomycetous fungi, like *Mucor circinelloides* (van Heeswijck, 1986), *Phycomyces blakesleeanus* (Revuelta & Jayaram, 1986), and *Absidia glauca* (Wostemeyer, Burmester & Weigel, 1987) autonomous replication of vectors was observed in most cases. Autonomous replication was also observed for a filamentous yeast species, *Trichosporon cutaneum* (Glumoff *et al.*, 1989) transformed with pAN7-1 (see above).

Fate of transforming DNA

As already mentioned, in most filamentous fungi vector DNA is integrated into the genome. Biochemical analysis of the DNA of transformants indicates that when a homologous selection marker is used, in general three types of integration events can occur: type I, integration of the vector by homologous recombination; type II, ectopic integration of the vector (or vector sequences) by non-homologous recombination; and type III, gene replacement. For most homologous selectable markers, predominantly homologous interactions (type I and III integrations) occur. However, in some cases type II transformants are preferentially found, e.g. in *A. nidulans* with the *amdS* gene (Wernars *et al.*, 1985) or the *prn* gene cluster (Durrens *et al.*, 1986), and in *Ascobolus immersus* with

predominantly type II transformants are observed when the *TRP-1* marker is used (Binninger *et al.*, 1987). Transformation of *Ascobolus immersus* with vector DNA linearised by cutting within the marker sequence or with circular single-stranded vector DNA preferentially results in type I integration events (Goyon & Faugeron, 1989).

In the case of heterologous selectable markers integration will always occur through non-homologous recombination, seemingly at random sites in the genome.

Genetic manipulation

The availability of different gene transfer systems with different charac-

interesting processes by isolation, characterisation and functional analysis of the genes and gene products involved. To perform these studies, specific vectors are constructed which facilitate genetic manipulation such as cloning of a gene by complementation of a mutation, gene disruption or gene replacement, and analysis of expression signals *in vivo*.

To illustrate the possibilities of genetic manipulation for molecular genetic studies examples will be given of research on *Aspergillus* that is in progress in our laboratory. The first example concerns experiments that have been performed to prove that a gene encoding a functional benzoate-*p*-hydroxylase gene of *Aspergillus niger* was cloned. In the second example, the application of different expression analysis vectors for a functional

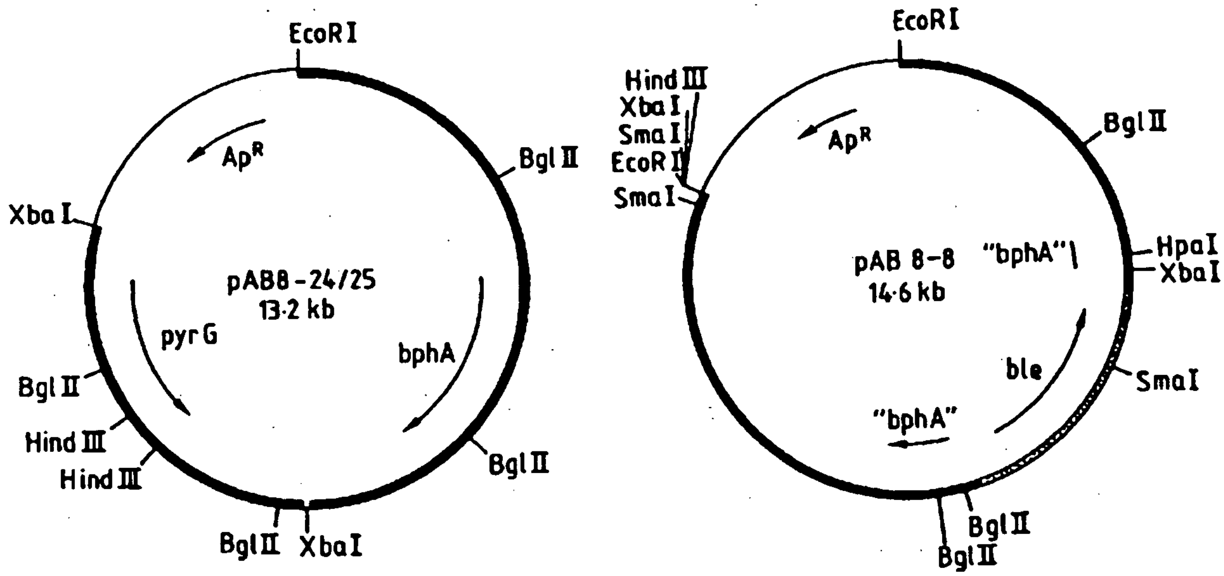

Fig. 1.2. Schematic representation of plasmid pAB8-8, which contains the disrupted *A. niger bphA* gene and the plasmids pAB8-24 and pAB8-25, which contain the *bphA* gene and, respectively, the wildtype or a mutant allele of the *pyrG* gene (Van Gorcom & Van den Hondel, 1988) of *A. niger* respectively. The disrupted *bphA* gene was obtained by replacing an *Eco*RV segment, located within the *bphA* gene, with the phleomycin resistance unit of pAN8-1. Thick line represents *A. niger* DNA, punctuated line *Streptoalloteichus hindustanus* DNA and thin line *E. coli* DNA; *ble*, phleomycin resistance gene; Ap^R, ampicillin resistance gene; '*bphA*', 5'- or 3'-terminal part of the *bphA* gene. Arrows indicate the direction of transcription.

analysis of the promoter region of the *Aspergillus* genes *gpdA*, *niaD* and *niiA* will be described. The third example deals with a study of the influence of different signal sequences on the efficiency of production of prochymosin in *A. niger*.

Cloning of a functional bphA *gene of* A. niger

Benzoate is metabolized by *A. niger* in a series of steps of which the first is *p*-hydroxylation of the aromatic ring of benzoate, carried out by benzoate-*p*-hydroxylase (BPH). Several mutants, disturbed in BPH activity, have been isolated (Boschloo & Bos, in preparation). These mutations were shown to belong to one complementation group, therefore the mutation was named *bphA*.

A cosmid clone, pAB8-1, containing the putative *bphA* gene, was isolated by differential hybridiaztion techniques. The gene was localized on a 6·2 kb *Eco*RI–*Pvu*II fragment, which was subcloned in pUC19, resulting in pAB8-22 (Van Gorcom *et al.*, 1990). Introduction of pAB8-1 or pAB8-22 DNA into an *A. niger bphA* mutant resulted in the restoration

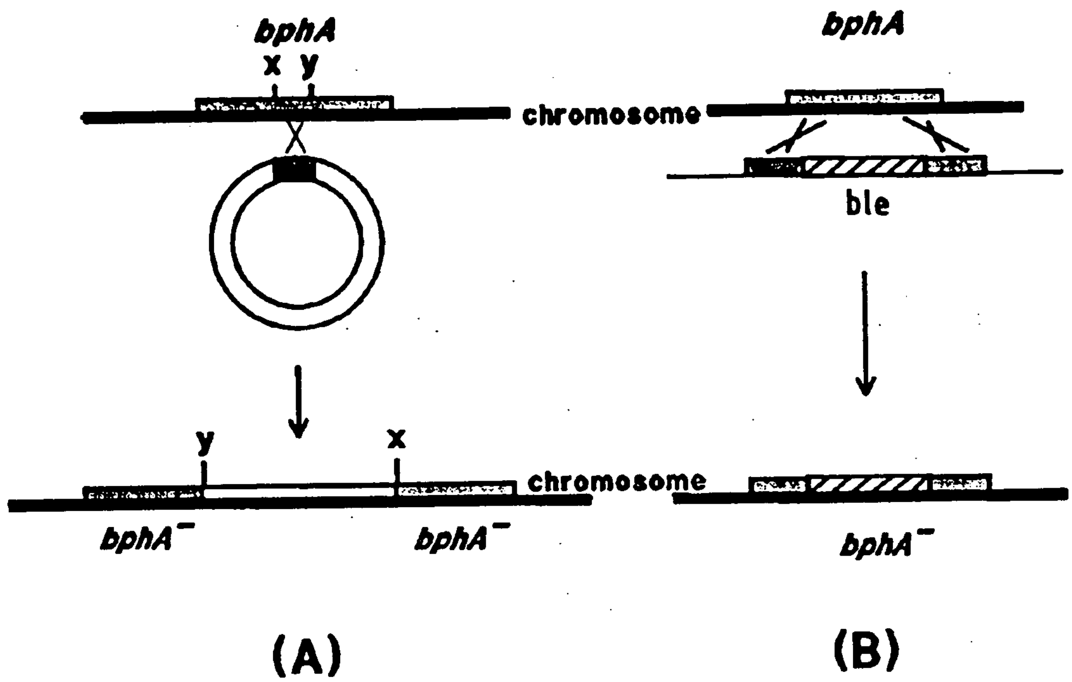

Fig. 1.3. Strategies to disrupt the *bphA* gene. Thin lines represent plasmid DNA and thick line chromosomal DNA. Shaded boxes represent the *bphA* gene or part of the gene. Hatched boxes represent the phleomycin resistance unit. Two restriction sites within the *bphA* gene are indicated with X and Y. (A) Disruption of the *bphA* gene by transformation with a plasmid which contains an internal restriction fragment. The recombination event shown results in formation of a duplication of *bphA* with the leftward copy lacking the 3' end of the gene and the rightward copy lacking the 5' end. (B) Disruption of the *bphA* gene by transformation with a linear fragment which contains a mutant allele of the *bphA* gene obtained by replacing an internal fragment with the phleomycin resistance unit. Recombination between the rightward and leftward homologous regions of the DNA fragment and the corresponding chromosomal regions results in a gene replacement of the wildtype gene with the mutant (disrupted) *bphA* allele.

---

of the ability to grow on benzoate, suggesting that the DNA fragment contained the *bphA* gene.

Although remote, it cannot be completely excluded that a suppressor of the *bphA* mutation had been cloned. One approach to exclude this possibility is to disrupt the cloned gene, replace the chromosomal gene by the disrupted equivalent and test for the inability to grow on benzoate.

Two methods regularly used in gene-disruption experiments are indicated in Fig. 1.3. In both cases the disruption vector contains a non-functional copy of the chromosomal gene to be disrupted. The method indicated in Fig. 1.3A requires knowledge about the exact position of the gene in the cloned fragment, whereas for the method indicated in Fig. 1.3B this is not necessary. To obtain an *A. niger* strain in which the

bphA gene was disrupted, the method indicated in Fig. 1.3B was chosen. For the disruption experiment, plasmid pAB8-8 was constructed (Fig. 1.2) which contains the non-functional *bphA* gene. In this plasmid part of the *bphA* sequences has been replaced by the phleomycin resistance unit of pAN8-1 (Mattern, Punt & Van den Hondel, 1988). Transformation of *A. niger* wild type with the isolated *Eco*RI fragment of pAB8-8 resulted in a number of phleomycin resistant colonies. Southern blot analysis revealed that in about 10% of the transformants a gene replacement had occurred. Further analysis showed that these transformants were not able to grow on benzoate as carbon source. This result confirms that the *bphA* gene and not a suppressor gene had been cloned.

Further evidence for cloning of the benzoate-*p*-hydroxylate-encoding gene was obtained from the DNA sequence of the *bphA* gene. Sequence comparison showed that the *bphA* gene encoded a cytochrome P450 mono-oxygenase, as might be expected.

Another important issue was the question whether the cloned gene was a functional copy of the *bphA* gene. To answer this question it was necessary to prove that the *bphA* mutation was complemented by the product of the cloned gene. Therefore an *A. niger bph*$^-$ strain was transformed with a plasmid containing the cloned gene and transformants were isolated in which the plasmid was integrated at an ectopic locus. Growth of these transformants on benzoate would indicate that a functional gene had been cloned. To achieve ectopic integration, the *A. niger pyrG* selection marker was cloned into pAB8-22 resulting in plasmid pAB8-24 (Fig. 1.2). Van Hartingsveldt *et al.* (1987) previously had found that a vector containing this selection marker is integrated at the *pyrG* locus in about 50% of *A. niger* transformants. However, Southern analysis of 48 transformants, obtained with pAB8.24, revealed that none of these transformants contained a vector integrated at the *pyrG* locus. Further analysis indicated that in most transformants the vector was integrated at the *bphA* locus.

To overcome the problem of preferential integration at the *bphA* locus, a mutant allele of the *A. niger pyrG* gene (Van Gorcom & Van den Hondel, 1988) was cloned in pAB8-22, resulting in pAB8-25 (Fig. 1.2). This mutant allele was constructed by introduction of a frameshift mutation which inactivates the marker gene. Transformation with the mutant allele as selection marker can result in Pyr$^+$ transformants only through type I or type III integration events. Analysis by Southern blotting of transformants obtained with pAB8-25 revealed that 14 out of 32 contained a single copy of this plasmid integrated at the *pyrG* locus. These transformants also showed a restored ability to grow on benzoate, indicating that, indeed, a functional *bphA* gene had been cloned. As demonstrated by Southern

analysis the other transformants resulted from a gene replacement at the *pyrG* locus. As expected, these transformants could not grow on benzoate.

Vectors for analysis of expression signals from **Aspergillus** *genes*

In both fundamental and applied molecular biological research on filamentous fungi the unravelling of the mechanism of gene expression is a very important topic. Interesting biological processes, such as development, differentiation and carbon and nitrogen metabolism are regulated at the level of gene expression. A wealth of classical genetic information is available for these processes, but, until recently, hardly any molecular genetic research was carried out. To provide an easy way to assay the expression and regulation of various genes, we developed reporter vectors for filamentous fungi (Van Gorcom *et al.*, 1986; Van Gorcom & Van den Hondel, 1988; Roberts *et al.*, 1989). In these vectors the analysis of fungal expression signals can be carried out by fusion of these signals to the *E. coli* reporter genes, *lacZ* or *uidA* encoding β-galactosidase and β-glucuronidase, respectively. The products of these genes can be assayed both qualitatively and quantitatively with easy and sensitive methods. For proper analysis of expression signals, it is essential that integration of one copy of the expression unit can be achieved at a specific location on the chromosome of the recipient. To fulfil this requirement, homologous selection markers were introduced in these vectors. An even higher (relative) frequency of homologous integration could be obtained by using mutant selection markers. These mutant selection markers were constructed by introduction of a frameshift mutation which inactivates the marker gene. Thus, only intragenic recombination (Type I or III integration) between the mutant selection marker on the vector and the mutant allele in the genome will result in prototrophic transformants. Although the transformation frequency obtained with this type of marker is much reduced (about 10-100 fold), Southern analysis of only a few transformants is sufficient to identify transformants with a single copy at the locus chosen (Table 1.5). Also, linearisation of the vector with a restriction enzyme which cuts in the marker gene, increases the relative frequency of Type I integration (Table 1.5).

The promoters of the *gpdA* genes of both *A. niger* and *A. nidulans* were studied in *A. niger* with the use of one of these vectors (Fig. 1.4). Single copy transformants, obtained with the two p_{gpdA}-*lacZ* fusion constructs, were assayed for β-galactosidase activity. In both cases efficient β-galactosidase expression was obtained (Table 1.6), whereas in untransformed strains or strains transformed with pAB94-12 (vector without promoter sequences inserted) no significant β-galactosidase activity was detected.

Table 1.5. Results of Southern analysis of *A. nidulans* transformants obtained with pAN5-d1 and derivatives

Vector[1]	Transformation frequency[2]	Percentage of LacZ$^+$ transformants[3]	Type of integration[4]		
			A	B	C
pAN5.d1	20-40	60%	0/19	4/19	15/19
pAN5.d1$_{(BglII\ digest)}$	40-100	90%	1/10	5/10	4/10
pAN5.d1$_{BglII}$	0·1-1	40%	5/10	3/10	2/10

[1] Vector pAN5-d1 contains a p_{gpdA}-*LacZ* fusion and the wildtype *argB* gene as selection marker for *Aspergillus* transformation (Punt *et al.*, 1990). The vector contains a unique *Bgl*II site in the coding region of the *argB* gene. Analysis of the transformants obtained with pAN5-d1, with a *Bgl*II digest of pAN5-d1 and with pAN5-d1$_{BglII}$, in which the unique *Bgl*II site was filled in with PolIK resulting in a frame shift mutation in the *argB* gene (Punt *et al.*, 1990), was carried out. Vectors were introduced into *A. nidulans* ArgB$^-$ (*methG2*, *biA1*, *argB2*).

[2] Transformation frequency is given as transformants per μg of vector DNA.

[3] The percentage of LacZ$^+$ transformants was determined by plating transformants on agar plates containing XGal (van Gorcom *et al.*, 1985). In all cases both LacZ$^+$ and LacZ$^-$ transformants were observed. The LacZ$^-$ transformants probably arose from gene replacement events.

[4] Southern analysis of a number of LacZ$^+$ transformants was carried out. The transformants were classified in three categories; A, single copy integration of the vector at the *argB* locus; B, multiple copy (tandem) integration of vector molecules at the *argB* locus; C, ectopic integration, in some cases in combination with single or multiple copy homologous integration.

A. nidulans and *A. niger* are both very efficient in *A. niger*. Further analysis of the organisation of the expression signals of the *A. nidulans* gene *gpdA* with similar vectors developed for *A. nidulans* is in progress in our laboratory (Punt *et al.*, 1990).

Recent research has shown that many fungal genes involved in developmental and metabolic pathways are organised as gene clusters (Gurr, Unkles & Kinghorn, 1988). Frequently, these clustered genes are coordinately expressed from divergently transcribing intergenic promoter regions. For the analysis of such intergenic regions a twin reporter vector was developed (Fig. 1.5). The usefulness of this vector can be inferred from the functional analysis of the intergenic region between the *A. nidulans* nitrate reductase (*niaD*) and nitrite reductase (*niiA*) genes. As shown in Table 1.7, both nitrate induction and nitrogen metabolite (ammonium) repression is observed for the reporter genes. Thus, the

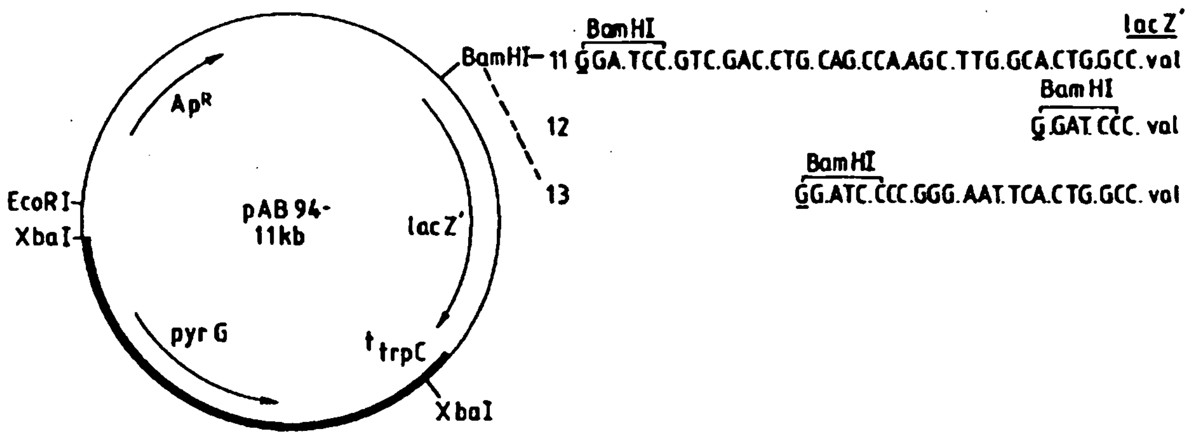

Fig. 1.4. Schematic representation of expression analysis vectors pAB94-11 to 13 for *A. niger* (Van Gorcom & Van den Hondel, 1988). The different vectors contain a unique *Bam*HI site in one of the three reading frames in front of the *lacZ'* gene (the protein coding region of the *E. coli lacZ* gene lacking the first eight codons). Thick line represents *A. niger* DNA (*Xba* I fragment) and *A. nidulans* DNA. Thin line represents *E. coli* DNA; t_{trpC}, terminator region of the *trpC* gene; Ap^R, ampicillin resistance gene; *pyrG*, mutant allele of the *A. niger pyrG* gene. Arrows indicate the direction of transcription.

Table 1.6. β-Galactosidase expression in *A. niger* transformants containing p_{gpdA}-*lacZ* fusion genes

Strain[1]	p_{gpdA}	βGAL activity[2]
AB4-1 [pAB94-53] 4	*A. niger*	8570
6		8380
7		7770
AB4-1 [pAB94-121] 4	*A. nidulans*	5160
13		5480
17		5350
AB4-1	–	<10

[1] Vectors pAB94-53 and pAB94-121, derivatives of pAB94-11/12/13, containing the promoter region of the *gpdA* gene of *A. niger* and *A. nidulans*, respectively, fused to the *LacZ* gene, were introduced into *A. niger* AB4-1 (*cspA*1, *pyrG*). Transformants with a single copy of the vector integrated at the *pyrG* locus were identified by Southern analysis.

[2] Enzyme activity is given in units (mg protein)$^{-1}$ and was measured as described

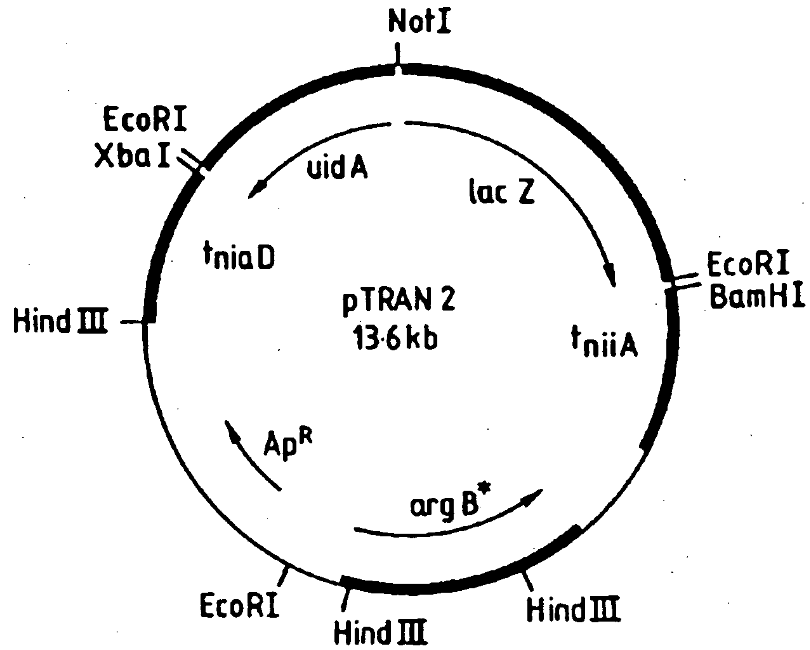

Fig. 1.5. Schematic representation of the twin reporter vector pTRAN2. Thin line represent pBR322 DNA; thick lines, *A. nidulans* DNA and *E. coli* DNA (*Eco*RI fragment) which contains the coding region of the *E. coli* genes *lacZ* and *uidA* both without translation initiation codon. A unique *Not*I site is placed between these genes; t_{niaD}, terminator region of the *niaD* gene; t_{niiA}, terminator region of the *niiA* gene; Ap^R, ampicillin resistance gene; *argB*$^+$, mutant allele of the *A. nidulans argB* gene containing a frameshift mutation. Arrows indicate the direction of transcription.

expression of the reporter genes *lacZ* and *uidA* faithfully represents the regulated gene expression of the genes *niaD* and *niiA* (Cove, 1979).

Expression of prochymosin

Several filamentous fungi are able to produce large amounts of extracellular proteins. Due to this property, several groups, including ours, are carrying out research to evaluate the potential of these strains for the production of heterologous proteins. One of the questions we addressed in our research on expression and secretion of heterologous, extracellular proteins in *A. niger* is the influence of different signal sequences on the efficiency of protein production/secretion. To answer this question experiments were performed to analyze the production of prochymosin with four different gene fusions (van Hartingsveldt *et al*., 1990). These fusions were placed under the control of the expression signals of the *A. niger* glucoamylase (*glaA*) gene. To facilitate proper comparison, transformants containing a single copy of the expression unit integrated at the *glaA* locus were isolated. For this purpose four different prochymosin expression vectors, pAB64-72 to pAB64-75 (Fig. 1.6), were used. Transformation of *A. niger* with *Hin*dIII-linearised pAB64-72 to 75 resulted in a number of hygromycin B resistant transformants. Southern analysis demonstrated

Table 1.7. Expression of the reporter genes in pTRAN2-1A transformants

	Relative enzyme activities[2]			
Strain[1]:	G324		SAA1012	
	βGUS	βGAL	βGUS	βGAL
proline	10	20	320	180
nitrate+proline	100	100	490	260
nitrate+ammonium	20	40	10	20
ammonium	2	10	2	4

[1] Vector pTRAN2-1A, a derivative of pTRAN2 (Fig. 1.4), containing the *A. nidulans niaD–niiA* intergenic promoter region was introduced in *A. nidulans* strains G324 (*wA3*, *yA2*, *methH2*, *argB2*, *galA1*, *sC12*, *ivoA1*) and SAA1012 (*fwA1*, *yA2*, *methH2*, *pabaA1*, *argB2*, *niiA-niaD* Δ509). Single copy transformants were identified by Southern analysis. In all cases the β-glucuronidase (βGUS) expression is a result of the activity of the expression signals of the *niaD* gene, and the β-galactosidase (βGAL) expression results from *niiA* gene expression signals.

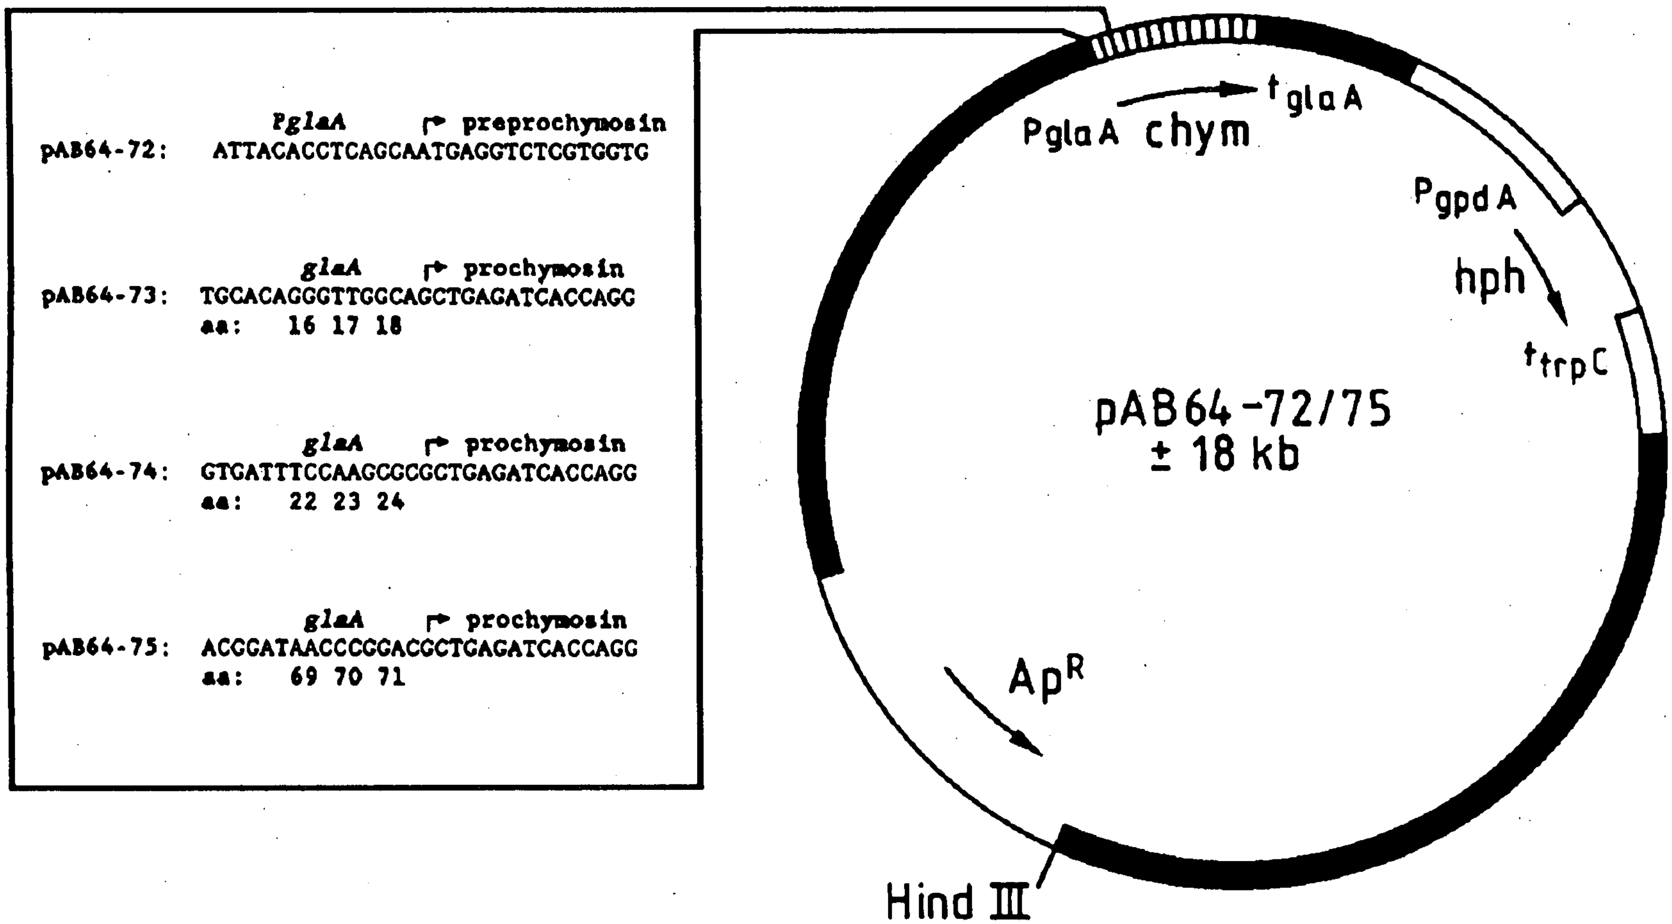
[2] Mycelial extracts were prepared from cells cultivated for 16 to 18 h in minimal growth medium with appropriate supplements and 10 mM of the indicated nitrogen sources. The enzyme activities were determined as described previously (Van Gorcom *et al.*, 1985; Roberts *et al.*, 1989) and are expressed relative to the activities of the G324[pTRAN2-1A] transformants induced with nitrate (= 100). In a representative experiment specific activities of 80 nmol *p*-nitrophenol min^{-1} (mg protein)$^{-1}$ for βGUS and 310 nmol *o*-nitrophenol min^{-1} (mg protein)$^{-1}$ for βGAL were found for the G324[pTRAN2-1A] transformants induced with nitrate.

Table 1.8. Analysis of prochymosin production in *A. niger*

Strain[1]	Signal peptide	Western[2] ($\mu g\ ml^{-1}$)	MCA[2] ($U\ ml^{-1}$)
AB64-72	signal sequence of prochymosin	6·2	8·6
AB64-73	signal sequence of *glaA*	11·3	19·5
AB64-74	signal sequence of *glaA* + 6 additional amino acids	4·1	3·2
AB74-75	signal sequence of *glaA* + 53 additional amino acids	10·2	19·1

[1] Vectors pAB64-72 to 75, linearised by cutting with *Hind*III, were introduced into *A. niger*. Transformants in which the *glaA* gene is replaced by the prochymosin fusion-genes, were identified by Southern hybridization (Van Hartingsveldt *et al.*, 1990).

[2] Medium samples from cells cultivated for 24 h in induction medium, were analyzed for the presence of prochymosin by Western blotting (Western) and



ɡ. 1.6. Schematic representation of four different prochymosin-expression vectors pAB64-72 to 75 (Van Hartingsveldt *et al.*, 90). Sequences at the glucoamylase-preprochymosin junction are indicated at the lefthand side. Thick lines represent *A. niger* NA from the *glaA* locus, open lines *A. nidulans* DNA, hatched lines preprochymosin DNA and thin lines *E. coli* DNA; p_{gpdA}, omoter region of the *gpdA* gene; p_{glaA}, promoter region of the *glaA* gene; t_{trpC}, terminator region of the *trpC* gene; t_{glaA}, terminator gion of the *glaA* gene; *hph*, hygromycin resistance gene; Ap^R, ampicillin resistance gene; *chym*, calf preprochymosin. Arrows dicate the direction of transcription.

that in about 10% of these transformants the resident *glaA* gene was replaced by the expression/secretion unit. Similar results were obtained with circular vector DNA, though with a three- to five-fold lower frequency.

Transformants which contained one copy of the expression/secretion unit were analyzed for prochymosin production 24 h after induction of the *glaA* promoter with starch (Van Hartingsveldt *et al.*, 1990). As shown in Table 1.8 similar levels of prochymosin were produced with pAB64-73 (18 amino acids of *glaA*) and pAB64-75 (71 amino acids of *glaA*). With 24 amino acids of *glaA* in front of prochymosin, or with the signal sequence of prochymosin itself, a lower production level was observed.

Although the reasons for the observed differences are obscure, our results clearly demonstrate that gene fusions containing different 5' sequences influence the production level of prochymosin.

Conclusions

During the last few years the development of gene transfer systems has been described for more than fifty fungal species. Transformation of most species could be achieved with heterologous auxotrophic markers or dominant selectable markers. Usually the marker gene is expressed from fungal, mainly *A. nidulans*, expression signals which were shown to be functional in most fungal species.

A number of strategies are now available for the development of gene transfer systems for hitherto poorly characterized fungal species. As illustrated in the first part of this chapter, these strategies comprise the following aspects. Firstly, methods for the introduction of vector DNA (Table 1.1). Secondly, a large number of auxotrophic and dominant selectable markers (Tables 1.2 to 1.4). Thirdly, efficient strategies for the isolation of auxotrophic mutant strains.

The main purpose for the development of gene transfer systems is application of these systems for molecular genetic studies. In the second part of this chapter several applications were illustrated with examples taken from research carried out in our laboratory. Genetic manipulation experiments were carried out (a) to disrupt the *bphA* gene of *A. niger*; (b) to analyze expression signals in *A. nidulans* and *A. niger*; (c) to direct expression-analysis vectors at specific sites of the genome such as the *argB* locus of *A. nidulans* or the *pyrG* locus of *A. niger* and (d) to perform gene replacement experiments in which the *glaA* gene of *A. niger* was replaced by chimeric prochymosin genes. These examples, as well as others described in the recent literature, indicate that most strategies and tools for genetic manipulation in filamentous fungi are now available, especially for *A. nidulans*, *A. niger* and *Neurospora crassa*. Extensive molecular genetic

studies of many interesting biological processes occurring in filamentous fungi can now be carried out using these strategies and tools.

Acknowledgements We wish to thank Peter Pouwels for critical reading of the manuscript and fruitful discussions. Gerry van Oossanen is acknowledged for typing the manuscript. Part of the work described in this chapter was financially supported by Gist-brocades, Delft, The Netherlands, DSM research, Geleen, The Netherlands and training grants from the EC.

I. INTRODUCTION

The purpose of this section is to provide a brief explanation of fungal taxonomy and a reference table for identifying major taxa. Remember that taxonomic schemes are neither static nor universally accepted. The one presented below follows Ainsworth (1971) and Ainsworth *et al.* (1973a,b). Other authorities may present quite different hierarchies and headings. Nomenclatural convention for fungi demands that subdivisions end in "-mycotina," classes in "-mycetes," orders in "-ales," and families in "-aceae." Depending on the authority and the scheme adopted, you may find the same group accorded differential rank. For example, the ascus-producing fungi may be viewed as a class, Ascomycetes, or as a subdivision, Ascomycotina.

If you are interested in exposure to other taxonomic arrangements and in learning more about mycology in general, consult one of the comprehensive, recent mycology texts such as Burnett (1968), Alexopoulos and Mims (1979), Ross (1979), or Moore-Landecker (1982).

The kingdom Fungi is divided here into two divisions. The Myxomycota, commonly called the "slime molds," are a varied group of organisms having a plasmodium at some point in their life cycle. One contemporary mycologist pointed out that "the very words *slime mold* reflect the confusion that has surrounded this group of organisms, because they are certainly not molds and they are not particularly slimy" (Ross, 1979, p. 178). A number of taxonomic questions remain unanswered as to whether the members of the Myxomycota really belong with the fungi.

Members of the division Eumycota, commonly called the "true fungi," usually have a filamentous or yeastlike form, and no plasmodium. Our scheme divides the group into five subdivisions. The Mastigomycotina and Zygomycotina constitute the "lower fungi"; the Ascomycotina, Basidiomycotina, and Deuteromycotina constitute the "higher fungi."

The lower fungi are distinguished by hyphae without cross-walls (nonseptate), the formation of asexual spores by cleavage of cytoplasm with sporangia, and include several groups that possess flagellated zoospores. For many years, the lower fungi were grouped together in a single class, the Phycomycetes. Phycomete means "algal fungus" and the name stems from the theory that these fungi were degenerate algae that had lost their chlorophyll. The term phycomycete no longer has official taxonomic status, but is still encountered in older texts and in works by authors who have not kept up with trends in fungal systematics. The classification we present here puts the lower fungi into two subdivisions, both of which encompass a diverse and composite group of organisms.

The subdivision Mastigomycotina includes species often identified with animals because of the defining characteristic of the group, motile spores. Many of these organisms are called water molds because of the prevalent aquatic growth habit.

Zygomycotina contains nonseptate fungi which lack a motile stage and are only rarely aquatic. Members of this subdivision exhibit gametangial fusion and zygospore formation.

Taxonomically, the higher fungi are easier to delineate. With the exception of the yeasts, they have septate hyphae and often produce elaborate fruiting bodies. They are divided here into three subdivisions: the Ascomycotina, the Basidiomycotina, and the Deuteromycotina. The Ascomycotina and Basidiomycotina are distinguished by their sexual spores; the Deuteromycotina reproduce entirely by asexual means.

The Ascomycotina form ascospores inside a specialized reproductive structure called an ascus. Two haploid nuclei fuse within the immature ascus and then the diploid fusion nucleus immediately undergoes meiosis, resulting in four haploid spores. One mitotic division usually ensues so that most members of the As-

comycotina have eight-spored asci. The retention of the products of meiosis within a single morphological structure has facilitated many elegant studies on chromosomal mechanisms of crossing-over. The three premier species for fungal genetics, *Aspergillus nidulans, Neurospora crassa,* and *Saccharomyces cerevisiae,* are all members of this group. Special features of fungal genetic analysis are discussed in detail by Esser and Kuenen, (1967), Burnett (1975), and Fincham *et al.* (1979).

The Basidiomycotina form sexual basidiospores on a basidium. Basidiospore formation closely resembles ascospore development, except that the spores are borne externally. Fusion of haploid nuclei results in a transient diploid that immediately undergoes meiosis to form four haploid basidiospores. An unusual cytological feature of the basidiomycete life cycle is the formation of a special binucleate cell called the dikaryon. This subdivision contains the majority of conspicuous, macroscopic fungi such as mushrooms, puffballs, and shelf fungi. It also contains the important plant pathogens known collectively as rusts and smuts.

The Deuteromycotina, or Fungi Imperfecti, are distinguished by the absence of any known sexual form. They reproduce largely by asexual conidiospores. Taxonomists consider this an ''artificial'' group, and often highlight this artificiality by using the prefix ''form'' with reference to the taxa within this subdivision (e.g., form-class, form-family, form-genus, form-species). Many species originally classified as imperfects are eventually shown to possess a sexual stage, usually within the Ascomycotina or, more rarely, within the Basidiomycotina. The sexual phase, also called the perfect stage or teleomorph, is given a separate name. The rules of botanical nomenclature specify that sexual names should have precedence over the asexual (also called imperfect or anamorphic) names. This creates both practical and philosophical problems. The genus names *Aspergillus, Penicillium,* and *Fusarium* are all imperfect epithets. According to the internationally adopted rules of nomenclature, any time a sexual stage is found for a member of one of these genera, the name of that species should be changed to that of the sexual form. For example, according to these rules, *Aspergillus nidulans* should be called *Emericella nidulans*. In practice, despite the fact that this species regularly forms ascospores, virtually everyone still calls it *Aspergillus nidulans*.

Many economically important fungi are classified in the Deuteromycotina. For more details about the taxonomy of *Aspergillus* see Raper and Fennell (1965); for *Fusarium* see Nelson *et al.* (1981); and for *Pencillium* see Pitt (1979) and Ramirez (1982). The majority of important human pathogens also belong to this group; see Rippon (1982). Finally, for a discussion of the issues and problems surrounding nomenclatural conventions in the Fungi Imperfecti, see Bennett (1985).

II. OUTLINE OF FUNGAL TAXONOMY

Kingdom: Fungi
Division: Myxomycota (plasmodium or pseudoplasmodium present)
Class: Acrasiomycetes ("cellular slime molds")
Example: *Dictyostelium*
Class: Myxomycetes ("acellular slime molds")
Example: *Physarum*
Division: Eumycota (assimilative phase typically filamentous or yeastlike)
Subdivision: Mastigomycotina (nonseptate mycelium, motile spores)
Examples: *Achlya, Allomyces, Blastocladiella, Phythium, Phytophthora, Saprolegnia*
Subdivision: Zygomycotina (nonseptate mycelium, zygospores)
Examples: *Absidia, Blakeslea, Mortierella, Mucor, Pilobolus, Rhizopus*
Subdivision: Ascomycotina ("sac fungi"; septate mycelium or yeast: sexual spores borne in an ascus)
Examples: *Saccharomyces, Saccharomycopsis (Yarrowia), Schizosaccharomyces; Neurospora, Podospora, Sordaria;* the sexual stages of both *Aspergillus* and *Penicillium; Ascobolus;* truffles and morels
Subdivision: Basidiomycotina ("club fungi"; septate mycelium or yeast; sexual spores borne exogenously on a basidium)
Examples: *Puccinia, Ustilago,* jelly fungi, rusts, smuts; *Agaricus, Coprinus, Schizophyllum,* mushrooms, puffballs, shelf fungi
Subdivision: Deuteromycotina (the Fungi Imperfecti; septate mycelium or yeast; no known sexual phase)
Examples: *Aspergillus, Fusarium, Penicillium; Candida, Histoplasma, Wangiella*

I. *Aspergillus nidulans* 538
II. *Neurospora crassa* 539
III. *Saccharomyces cerevisiae* 540
IV. Other Fungi 542
References 542

Recommendations for uniform conventions of genetic nomenclature have been published for bacteria (Demerec *et al.*, 1966), *Aspergillus nidulans* (Clutterbuck, 1973), *Saccharomyces cerevisiae* (Sherman, 1981), and *Neurospora crassa* (Perkins *et al.*, 1982). In this volume, we make no attempt to impose a uniform standard of genetic symbols, but rather allow our authors to utilize the conventions of their particular organism and laboratory.

Although the designations for gene symbols and phenotypes are not the same for bacteria, yeasts, and molds, enough similarity exists to mislead the unwary reader. Since the publication of the proposals for bacterial genetics by Demerec *et al.* (1966), most primary gene symbols have been designated by three-letter, italicized symbols (e.g., *arg* for a locus affecting arginine biosynthesis). Some *Neurospora* and *Aspergillus* symbols predate the proposals for standardization of genetic nomenclature in bacteria and have fewer or more than three letters.

The conventions for distinguishing different loci that produce the same phe-

notypic change show minor, but confusing, variation from system to system. In bacteria and *A. nidulans* an italicized capital letter immediately follows the three-letter symbol (*argA*, *argB*, etc.), while in yeast nonhyphenated numbers are used (*arg1*, *arg2*, etc.). In *N. crassa*, hyphenated numbers are used to distinguish loci (*arg-1*, *arg-2*, etc.). In yeast, hyphenated numbers designate alleles (*arg1-37*); in *A. nidulans*, unhyphenated numbers designate alleles (*argA2*) and hyphenated numbers designate unmapped mutants (*arg-51*).

The conventions for phenotype, dominance, mating-type loci, designation of wild type, and other genetic symbols also show subtle differences between the systems. The most important recommendations from Clutterbuck (1973), Sherman (1981), and Perkins *et al.* (1982) are summarized in Sections I–III. Some representative examples are given to illustrate each system. Section IV cites a few additional systems of fungal genetic nomenclature. See the references for more complete explanations of all these nomenclatural conventions.

I. *ASPERGILLUS NIDULANS*

The recommendations for the nomenclature and conventions used for *A. nidulans* follow those of bacterial genetics and are published in Clutterbuck (1973). All genetic loci and mutants introduced subsequent to this publication are designated by three-letter symbols in italics (e.g., *arg*). Older symbols, previously adopted in the literature, are retained and consist of one to five italic letters (e.g., *y* = yellow; *panto* = pantothenic acid requirement). Nonallelic loci that have the same primary symbols are distinguished by an italic capital letter following the symbol, e.g., *argA*, *argB*. Alleles are distinguished by italic serial mutant numbers after the symbol and locus letter, e.g., *argA1*, *argA2*. Where the allelic relationships of a mutant have not yet been determined, the capital letter is replaced by a hyphenated number (e.g., *arg-51*). Mitochondrial gene symbols are enclosed in square brackets, e.g., [*oliA1*].

Wild-type alleles are indicated by a superscript "plus," e.g., *argA*$^+$. Occasionally, dominant mutants are designated by capitalizing the first of the three letters in a symbol (*Acr* for acriflavine resistance). In general, dominance is not indicated in the primary gene symbol. Symbols for phenotypes are distinguished from symbols for genes. Often the phenotype is simply written out in unabbreviated fashion (e.g., "arginine requirement"); alternatively, a nonitalic version of the gene symbol with the first letter capitalized is used, e.g., Arg$^-$.

Suppressors used to be designated by complex symbols including the locus and/or allele suppressed, e.g., *suA1adE20*, but now simple symbols are encouraged, e.g., *suaA1* allele-specific, locus-nonspecific suppressor. It is important to note that the wild-type, nonsuppressing allele is designated with a symbol "plus," as in *suaA*$^+$, opposite to the usage for bacteria.

Superscripts are used to indicate mutants with specific properties; for instance, *areA*^{d}*18* is an *areA* allele giving derepressed phenotypes for ammonium-repressed genes, while *areA*^{r}*1* gives correspondingly repressed phenotypes.

The following examples illustrate the conventions used in the genetic nomenclature for *A. nidulans*:

argA	A specific locus or mutation that produces a requirement for arginine as the phenotype
argA^{+}	The wild-type allele
argA2	A specific allele or mutation in the *argA* gene
arg-51	An arginine-requiring mutant not yet tested for allelism, whose locus is unknown
Arg^{+}	A strain not requiring arginine
Arg^{-}	A strain requiring arginine

A list of *A. nidulans* loci is given in Clutterbuck (1974), genetic maps are given in Clutterbuck (1984), and the mitochondrial genome is summarized by Spooner and Turner (1984).

II. *NEUROSPORA CRASSA*

A summary of conventions, gene symbols, and map locations of *N. crassa* genes is presented in Perkins *et al.* (1982), following Barratt and Perkins (1965). These conventions antedate bacterial genetic nomenclature and more closely follow those of *Drosophila*. Three-letter gene symbols are used most frequently, but symbols of one to four letters are also found. Two-letter symbols are quite common (e.g., *ad,* adenine requirement; *qa,* quinate utilization). Recessive gene symbols are written entirely in lowercase italics. When the mutant allele is known to be dominant, the first letter is capitalized (e.g., *Sk,* Spore killer).

Symbols without superscripts are used to represent mutant alleles. The same symbol with a superscript "plus" designates the wild-type allele, e.g., *ad*$^{+}$. Alleles differing in resistance or sensitivity, or allelic series having no definitive wild type, may be distinguished by other superscripts (e.g., *cyh-1*^{R}, cycloheximide resistance; *cyh-1*^{S}, cycloheximide sensitivity).

Nonallelic loci are distinguished from one another by numbers, separated from the symbol for the locus by a hyphen, e.g., *ad-1, ad-2*. The use of hyphens to distinguish nonallelic gene symbols differs sharply from the conventions for bacteria, *Aspergillus,* and yeast. In *Neurospora,* the allele number is "not usually displayed with the gene symbols, except when necessitated by the use of several alleles, when it is included in parentheses after the full locus symbol, e.g. *pyr-3* (KS43), or when a new mutant gene has not yet been assigned a locus number pending tests for allelism with similar genes at previously established

loci. In the latter situation, a mutant gene is temporarily designated by an appropriate letter symbol followed immediately by the allele number in parentheses, e.g. *ilv(STL6)*" (Perkins *et al.*, 1982, p. 427).

Mating-type alleles are called *A* and *a*. Suppressors are designated *su*, followed immediately by the symbol of the suppressed gene in parentheses; nonallelic suppressors of the same gene are distinguished by hyphenated numbers following the parentheses, e.g., *su(met-7)-1*, *su(met-7)-2*. Following the *Drosophila* convention, su^+ designates the wild type and *su* designates the mutant suppressor allele.

The following examples illustrate the major conventions used in the genetic nomenclature for *N. crassa:*

arg	Any locus or mutation that produces a requirement for arginine as the phenotype
arg-1	A specific locus that produces a requirement for arginine
arg-1$^+$	The wild-type allele of the *arg-1* gene
arg-1 (JWB7)	A specific allele of the *arg-1* gene
arg (JWB22)	An arginine-requiring mutant not yet tested for allelism, whose locus is unknown
Arg$^+$	A strain not requiring arginine
Arg$^-$	A strain requiring arginine

The Perkins *et al.* (1982) reference includes a detailed compendium of *N. crassa* loci and linkage maps. The maps are updated in Perkins (1984) and the mitochondrial genome is summarized by Collins and Lambowitz (1984).

III. *SACCHAROMYCES CEREVISIAE*

The recommendations for the nomenclature and conventions used in yeast genetics are summarized by Sherman (1981) and Sherman and Lawrence (1974). Gene symbols are consistent with the proposals of Demerec *et al.* (1966), whenever possible, and are designated by three italicized letters, e.g., *arg*. Contrary to the proposals of Demerec *et al.* (1966), the genetic locus is identified by a number (not a letter) following the gene symbol, e.g., *arg2*. Dominant alleles are denoted by using uppercase italics for all three letters of the gene symbol, e.g., *ARG2*. Lowercase letters symbolize the recessive allele, e.g., the auxotroph *arg2*. Wild-type genes are designated with a superscript "plus," (*sup6*$^+$ or *ARG2*$^+$). Alleles are designated by a number separated from the locus number by a hyphen, e.g., *arg2-14*. Locus numbers are consistent with the original assignments; however, allele numbers may be specific to a particular laboratory.

Phenotypic designations are written out or denoted by cognate symbols, with-

out italics, and by the superscripts "plus" and "minus." For example, independence of and requirement for arginine can be symbolized, respectively, as Arg^+ and Arg^-.

Gene clusters, complementation groups within a gene, or domains within a gene having different properties are designated by capital letters following the locus number, e.g., *his4A, his4B*. (Note that in the conventions of Demerec *et al.*, 1966, capital letters following the gene symbol designate different loci.)

Wild-type and mutant alleles of the mating-type and related loci do not follow the standard rules. The two wild-type alleles at the mating-type locus are designated *MAT***a** and *MAT*α. The two complementation groups of the *MAT*α locus are denoted *MAT*α*1* and *MAT*α*2*. Mutations of the *MAT* genes are denoted, e.g., *mat***a***-1*, *mat*α*1-1*. The wild-type homothallic alleles at the *HMR* and *HML* loci are denoted *HMR***a**, *HMR*α, *HML***a**, and *HML*α. Mutations at these loci are denoted, e.g., *hmra-1*, *hml*α*-1*.

The following examples illustrate the conventions used in the genetic nomenclature for *S. cerevisiae:*

ARG2	A locus or dominant allele
arg2	A locus or recessive allele that produces a requirement for arginine as the phenotype
ARG2$^+$	The wild-type allele of this gene
arg2–9	A specific allele or mutation at the *ARG2* locus
Arg^+	A strain not requiring arginine
Arg^-	A strain requiring arginine

For information on yeast mitochondrial genomes, see Grivell (1984).

For most structural genes that code for proteins, the nonmutant ("wild-type") allele is usually dominant to the mutant form of a gene. In yeast, the convention for dominant, "normal" genes utilizes capitalized italic symbols such as *HIS4* and *LEU2*. In traditional genetics, we learn about genes through their mutations, and linkage maps are created by following mutant alleles in crosses. Published linkage data, therefore, consist of gene symbols for the mutant, usually recessive, alleles [e.g., on linkage group III, *his4* and *leu2*. Those mutant alleles that are dominant to their nonmutant, "normal" alleles will appear on linkage maps in capital letters (*SUP22* and *FLD1* on chromosome IX)]. In addition, capital letters are used to represent dominant wild-type genes that control the same character and that are used for mapping (*SUC2, SUC1*, etc.), as well as DNA segments whose locations have been determined by a combination of recombinant DNA techniques and classical mapping procedures, e.g., *RDN1*, the segment encoding ribosomal RNA.

Detailed yeast linkage maps have been published by Mortimer and Schild (1980, 1984).

IV. OTHER FUNGI

Genetic conventions in other fungi sometimes follow one of the systems outlined above. In the past, workers with "less popular" species tended to follow some version of the bacterial–*A. nidulans* conventions; more recently, the yeast system has been gaining in popularity. For example, yeast conventions are used for the plant pathogen *Cochliobolus heterostrophus* (O. Yoder, personal communication). Regrettably, many workers adopt idiosyncratic symbols.

Both the "Handbook of Genetics, Vol. 1, Bacteria, Bacteriophages, and Fungi" (King, 1974) and "Genetic Maps 1984" (O'Brien, 1984) contain information about some of the better studied of the less popular fungi. Specific references, in alphabetic order by genus, follows:

Ascobolus immersus (Decaris *et al.*, 1974)
Dictyostelium discoideum (Newell, 1984)
Phycomyces (Cerdá-Olmedo, 1974)
Podospora anserina (Esser, 1974; Marcou *et al.*, 1984)
Schizosaccharomyces pombe (Gutz *et al.*, 1974)
Sordaria (Olive, 1974)
Ustilago maydis (Holliday, 1974)

Two species of Basidiomycetes, *Coprinus radiatus* and *Schizophyllum commune,* have been studied intensively, especially with respect to their incompatibility factors. Consult the following references for more information about these systems: Raper (1966), Guerdoux (1974), Raper and Hoffman (1974), and Schwalb and Miles (1978).

ACKNOWLEDGMENTS

We thank A. J. Clutterbuck, R. Metzenberg, D. Perkins, and F. Sherman for reviewing sections of this appendix.

Aspergillus nidulans, 43, 67, 68, 71, 72, 73, 74, 75, 281, 282, 283, 284, 286, 288, 290, 291, 295, 298, 299, 309, 310, 312, 313, 314, 322, 334, 350, 362, 518, 533, 537, 538
Aspergillus niger, 67, 72, 268, 350, 361, 362, 363, 365, 366, 368, 372, 497, 507, 522
Aspergillus orchraceus, 375
Aspergillus oryzae, 49, 51, 371, 376, 522
Aspergillus parasiticus, 49
Aspergillus sojae, 49
Aspergillus tamarii, 49, 51
Aspergillus terreus, 365, 375
Aspergillus ustus, 370
Aspergillus wentii, 51
ATP synthetase, 347
ATPase 6, 70, 72, 73, 75, 76, 78, 79, 86
ATPase 8, 71, 72, 75, 78
ATPase 9, 71, 75, 79, 82, 83, 88
Aureobasidium pullulans, 372, 373
Autogenous regulation, 315
Autolysis, 37
Autonomous plasmid, 167, 177, 183, 280
Autonomous replication, 198
Autonomously replicating plasmid (YRp31), 208
Auxotrophic mutants, 3, 4, 6, 127, 207, 478

B

Balanced interactions, 304
Balanced lethal genotypes, 298
Base pairing, 41
Basidiomycotina (Basidiomycetes), 36, 52, 53, 55, 532, 534
Benomyl, 10, 131
Beta-carotene, 380
Beta-galactosidase, 274
Beta-galactosidase gene, 179, 180, 219
Beta-glucosidase, 502, 506, 507
Biomass, 496
Biopolymers, 372
bla gene, of *E. coli*, 503
Blakeslea trispora, 380, 534
Blastocladiella emersonii, 49, 534
Brettanomyces abstines/B. custersii, 51
Brettanomyces anomalus/B. clausenii, 51
Brettanomyces galactosidase, 151
Brettanomyces tubulin, 10
Britten and Davidson, 325
Brute force cloning method, 350

C

cAMP-binding proteins, 452
cAMP-dependent kinases, 452
Candida, 47, 48, 534, 364, 381
Candida albicans, 379, 476
Candida blankii, 367
Candida brumptii, 367, 368
Candida cloacae, 375
Candida guilliermondii, 371
Candida humicola, 370
Candida hydrocarbofumarica, 367
Candida lipolytica (Yarrowia), 363, 364, 368, 376, 377, 379
Candida maltosa, 461
Candida pelliculosa, 369
Candida polymorpha, 382
Candida rugosa, 367, 368
Candida sp. no. 107, 375
Candida stellatoidea, 477, 483, 485, 486
Candida tropicalis, 370, 477, 478, 483, 485
Candida utilis, 367, 369, 371, 377, 378, 381
Candida zeylanoides, 364
CAN1, 128, 199, 218
Capsule, 471
Carbamoyl phosphate, 281
Carbamoyl-phosphate synthetase, 288
Carbohydrases, 494, 505, 508
Carbon catabolite repression, 22, 322, 323, 328, 329
Carbon sources, 323
Carotenoids, 379, 380
Cascade experiments, 349
Cascade, of regulatory genes, 22
CAT, 219
CAT cartridges, 219, 220
cat gene, 219
catabolic dehydroquinase, 248
CBHI, 505, 506
CBPI locus, 89
cdc6, 131
CDC8, 180

The *YJU3* ORF encodes a polypeptide of 313 amino acids with a predicted molecular weight of 35,549 Da. Computer-aided comparisons of the predicted amino-acid sequence of *YJU3* to sequence databases revealed no sequences with statistically significant similarity to *YJU3*. A null allele of the *YJU3* gene was made by inserting the *LEU2* marker gene within the coding region, at the *Bgl*II site (Figure 2B). The disrupted *YJU3* gene was then used to transform a haploid Leu⁻ strain. Southern analysis of Leu⁺ transformants confirmed the predicted structure of the disrupted *YJU3* gene by showing the presence of restriction endonuclease sites diagnostic of the transplacement. These Leu⁺ transformants grew normally and lacked obvious phenotypic abnormalities, suggesting that *YJU3* is not essential to mitotic growth.

ACKNOWLEDGEMENTS

We gratefully acknowledge Dr John Sgouros (MIPS, Munich, Germany) and Dr Elisabetta Balzi (University of Louvain, Louvain-la-Neuve, Belgium) for their help in sequence analysis. This work was supported in part by grants to A. G. from the Services de la Politique Scientifique: Action Sciences de la Vie and by the Fonds National pour la Recherche Scientifique, Belgium.

INTRODUCTION

The yeast *Saccharomyces cerevisiae* has several properties which have established it as an important tool in the expression of foreign proteins for research, industrial or medical use. As a food organism, it is highly acceptable for the production of pharmaceutical proteins. In contrast, *Escherichia coli* has toxic cell wall pyrogens and mammalian cells may contain oncogenic or viral DNA, so that products from these organisms must be tested more extensively. Yeast can be grown rapidly on simple media and to high cell density, and its genetics are more advanced than any other eukaryote, so that it can be manipulated almost as readily as *E.coli*. As a eukaryote, yeast is a suitable host organism for the high-level production of secreted as well as soluble cytosolic proteins.

Most yeast expression vectors have been based on the multi-copy 2µ plasmid and contain sequences for propagation in *E.coli* and in yeast, as well as a yeast promoter and terminator for efficient transcription of the foreign gene (Figure 1). The recen

rapid expansion in yeast molecular genetics has led to a great increase in our understanding of these components, and as a result there is now a bewildering choice of promoter systems and methods for propagating foreign DNA in yeast. In many cases ingenious new approaches have been employed, for example in increasing the strength of native promoters or the stability of expression vectors. We will attempt to review the choices now available and how they relate to different requirements.

Insertion of a foreign gene into an expression vector does not guarantee a high level of the foreign protein; gene expression is a complex multi-step process and problems can arise at numerous stages, from transcription through to protein stability. In the past, heterologous gene expression has often been treated empirically—a number of host organisms might be tested for successful expression and low yields or failures would be passed over. Frequently, inappropriate conclusions had been made, for example about relative promoter strengths, simply from knowledge of the input vector and the final steady-state level of the foreign protein. However there is now considerable accumulated experience on foreign gene expression in yeast. In many instances this has led to the identification of a particular problem at a specific stage in the chain of events, and then often to its solution. Among eukaryotes yeast offers unparalleled scope for solving such problems on account of the power of classical and molecular genetics combined. We have attempted to draw together examples of this from the literature, and from our own experience. These should be helpful in predicting and solving problems with new genes, and should be applicable, in many cases, to other expression systems, prokaryotic and eukaryotic.

The secretion of foreign proteins which are naturally secreted is often necessary for their correct folding, and is highly advantageous because of the initial purity of the product in the substantially protein-free culture medium. Although there have been several commercial successes using yeast, the area has frequently presented problems, especially for larger proteins. Despite increased understanding of the processes of secretion, the greatest success in improving yields in recent years has been with a classical random mutagenesis approach.

A number of other yeasts have become important host organisms for foreign gene expression because of advantages in promoter strength, secretion efficiency, or ease of growth to high cell density. In the future some of these will often be used in preference to *S.cerevisiae*. We have therefore devoted a substantial section to discussing other yeasts, particularly *Pichia pastoris* in which there are many examples of high-level expression.

An area which is frequently ignored by molecular biologists but which must be considered from the outset in vector design is the physiology of foreign gene expression. This includes the physiology of growth to high cell density and promoter induction, as well as the effect of expressing a foreign protein on host cell metabolism. We have gathered examples of the toxicity of foreign proteins and its effect in causing selection of genetic variants expressing lower yields; in many cases these effects can be controlled. Finally, we will discuss the considerations involved in industrial scale-up and fermenter optimization through examples with different promoter systems of *S.cerevisiae* and with *Kluyveromyces lactis* and *P.pastoris*.

TRANSFORMATION AND SELECTABLE MARKERS

Transformation

The first methods for the transformation of *S. cerevisiae* involved enzymatic removal of the cell wall to produce sphaeroplasts which could take up DNA on treatment with calcium and polyethylene glycol.[24,168] Transformants were then plated out in a selective, isotonic top agar for regeneration of the cell wall. A more convenient method was later developed in which intact yeast cells were made competent by treatment with lithium ions.[189] This method is now widely used despite the fact that it gives lower frequencies; a variation using DMSO increases frequency 25-fold.[167] More recently a third approach, electroporation, has been used, and a highly efficient method has been reported by Meilhoc *et al.*[252]

The process of transformation appears to be somewhat mutagenic, both for the host cell[342] and for the introduced DNA.[72] However the frequency of mutation is low enough that it should not be a major concern here. Also, Danhash *et al.*[83] have reported that transformation induces a heritable slow-growth phenotype in *S.cerevisiae*.

An important factor to consider in foreign gene expression is the frequent wide variation in the productivity of different transformants when 2μ vectors are used. This appears to be due to an unexplained stable variation in plasmid copy number between different transformants.[237,292] Clearly it is therefore important to analyse a number of transformants when optimizing expression.

Table 1. Selectable markers for *S.cerevisisae* transformation.

Marker	Auxotrophic/ dominant	Comments
HIS3	A	
TRP1	A	Selection possible in CAA
LEU2	A	*LEU2*-d for high copy number selection
URA3	A	(a) Selection possible in CAA (b) *URA3*-d for high copy number selection[237] (c) Counter-selection using 5-FOA[37] (d) Autoselection in *fur1* (5-FU-resistant) strain[237,304]

CAA, Casamino acids.

Auxotrophic selection markers

The first and most commonly-used markers for the selection of transformants were *LEU2*, *TRP1*, *URA3*, and *HIS3* used in corresponding mutant strains which are auxotrophic for leucine, tryptophan, uracil and histidine, respectively[24,308,370,382] (Table 1). Such strains are widely available, and some contain non-reverting mutant alleles constructed to give low background rates in transformations. Continued selection requires the use of minimal growth media lacking the relevant nutrient. It is worth noting that *TRP1* and *URA3* vectors can be selected in the presence of acid protein hydrolysates (which lack tryptophan and uracil, e.g. casamino acids) that are often added to semi-defined media in order to enhance growth rates.

A frequently-used variant of *LEU2*, *LEU2*-d,[24] has a truncated promoter and is poorly expressed, so that its selection gives rise to very high plasmid copy numbers.[109] Direct selection of transformants with this marker is inefficient and requires the sphaeroplast method, though low levels can be obtained using the lithium method, if cells are incubated overnight in non-selective medium prior to selection. Vectors which contain both *LEU2*-d and another marker, e.g. *URA3*, can be maintained at either high or low copy number depending on the selection used. Loison *et al.*[237] used an expression vector containing these markers for the schistosomal antigen P28-I and obtained product at 3% of total cell protein (t.c.p.) in uracil-deficient medium or 25% in leucine-deficient medium. Loison *et al.*[237] also constructed a promoter-defective *URA3* allele, *URA3*-d, which gives high copy number in uracil-deficient medium.

URA3 and *LYS2* are particularly versatile in that there are also methods for counter-selection of the marker. Thus *ura3*⁻ cells can be selected for their resistance to the toxic antimetabolite 5-fluoro-orotic acid,[37] and *lys2*⁻ cells can be selected for resistance to α-aminoadipic acid.[17,61,121] These methods can be

(b) pWYG7L has intact 2μ *ORI, STB, REP1* and *REP2*, the *GAL7* promoter, and uses the *FLP* terminator; foreign genes are inserted in the polylinker with their 5' ends at the *Bam*HI or *Nco*I site.

used either to select mutations in prototrophic strains or to select for plasmid loss in transformants.

Dominant selectable markers

Dominant markers are useful in that they increase the range of host strains that can be tested to include prototrophic and industrial strains of *S.cerevisiae*, and can be used for selection in rich medium. Since most strains are sensitive to the aminoglycoside antibiotic G418, the G418-resistance marker, encoded by the *E.coli Tn903* transposon, can be used, though it is inefficient in direct selection of transformants.[200,400] Frequencies are acceptable provided transformants are incubated overnight in non-selective medium prior to plating out on G418 agar.[23] Use of glycerol rather than glucose as the carbon source during selection reduces the number of untransformed G418-resistant mutant colonies that arise.[178] Multiple copies of the *Tn903* G418-resistance marker are needed to confer resistance in yeast cells unless a yeast promoter is used, in which case it is active in single copy.[154] It may be prudent to omit selection with antibiotics which affect ribosomes, such as G418, during induction of expression vectors due to the possibility of increased amino acid misincorporation. Other antibiotic-resistance markers that have been used successfully in yeast are hygromycin B[150] and chloramphenicol-resistance.[153]

Copper-resistance in yeast is conferred by multiple copies of the *CUP1* gene and can therefore be used as a dominant marker in sensitive (*CUP1*^{s}) strains.[122] It has proved useful on multi-copy vectors, particularly with industrial strains.[159] Two other markers which can be used for vector copy number amplification by increased drug selection are the herpes simplex virus thymidine kinase gene[418,419] and dihydrofolate reductase.[256]

Autoselection

A number of 'autoselection systems' have been devised to ensure that plasmid selection is maintained, irrespective of culture conditions. Bussey and Meaden[50] showed that expression of a cDNA encoding the yeast killer toxin and immunity gene could be used for self-selection of transformants of laboratory or industrial yeasts since plasmid-free cells are killed by plasmid-containing cells. Another system has used the *Schizosaccharomyces pombe* triosephosphate isomerase gene to stabilize plasmids in *S.cerevisiae* cells lacking the active gene, during growth on glucose.[208]

Loison *et al.*[236] used *ura3 fur1* strains as hosts for plasmids containing the *URA3* gene. These are non-viable since they are blocked both in the *de novo* and salvage pathways for uridine 5'-monophosphate synthesis; maintenance of a *URA3* plasmid is then obligatory for viability even in uracil-containing media. Since the double mutant without plasmid is non-viable, the transformant was obtained by mating a *fur1* strain with a *ura3* strain containing the *URA3* plasmid, and selecting the plasmid-containing *ura3 fur1* progeny. Subsequently, Loison *et al.*[237] were able to directly isolate spontaneous *fur1* mutants from *ura3* cells transformed with a *URA3* plasmid by selecting for resistance to 100 μg/ml 5-fluorouracil and then screening resistant colonies for resistance to 300 μg/ml 5-fluorouridine. We have found that it is possible to generate stable *URA3* transformants by a single direct selection on 1·3 mg/ml (10 mM) 5-fluorouracil to which only *fur1* mutants should be resistant[304] (Figure 2).

EPISOMAL VECTORS

Extra-chromosomal replicons are based either on plasmids containing yeast autonomous replication sequences (*ARS*),[54] which function as origins of replication, or on the native 2μ circle of *Saccharomyces*.[24] A comprehensive listing of both episomal and integrating vectors has been compiled by Parent *et al.*[281]

ARS *vectors*

ARS vectors are present in multiple copies per cell (1 to 20) but are mitotically highly unstable, plasmid-free cells accumulating at a rate of up to 20% per generation without selection, due to inefficient transmission to daughter cells during cell division.[264] Even when grown under selection the proportion of plasmid-containing cells can be very low, giving a correspondingly low average copy number. *ARS* vectors can be stabilized by the addition of yeast centromeric sequences (*CEN*), but the copy number is then reduced to 1 or 2 per cell.[75] In practice *ARS* vectors are hardly ever used for foreign gene expression, and *ARS/CEN* vectors are only used where low-level expression is desired.

2μ-based vectors

By far the most commonly-used expression vectors are *E.coli*-yeast shuttle vectors based on 2μ.[8,44,281] 2μ is a 6·3 kb plasmid present in most

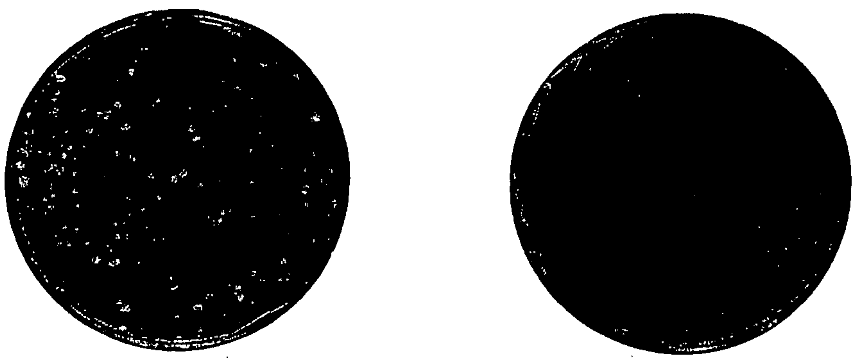

Figure 2. Stability of a *URA3* vector in wild-type and 5-fluorouracil-resistant strains. A β-galactosidase expression vector (pWYG4-*lacZ*) was introduced into strain KY117 and spontaneous mutants resistant to 10 mM-5-fluorouracil were selected.[304] Wild-type (1) and mutant (2) transformants were grown for ten generations in non-selective inducing medium, then plated out on non-selective plates containing XGal and galactose to assay for β-galactosidase expression. White colonies, indicating plasmid-loss, were not present with the mutant strain. This indicates autoselection of the vector in the 5-fluorouracil-resistant strain.

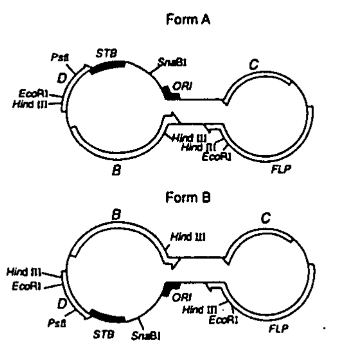

Figure 3. The two forms of the 2μ plasmid. *Cis*-elements are shown as filled boxes and genes by open boxes, inverted repeat regions are aligned; see text for a detailed description.

Saccharomyces strains at about 100 copies per haploid genome[128,265,395] (Figure 3). The plasmid encodes four genes: *FLP* (or *A*), *REP1* (or *B*), *REP2* (or *C*) and *D*. In addition, 2μ contains an origin of replication (*ORI*, which behaves as a typical *ARS* element), the *STB* locus (required *in cis* for stabilization), and two 599 bp inverted repeat sequences. *FLP* encodes a site-specific recombinase which promotes flipping about the FLP recombination targets (FRT) within the inverted repeats, so that cells contain two forms of 2μ, A and B.

Despite the fact that it confers no known phenotype and may indeed be slightly disadvantageous to the host cell,[129,251,397] 2μ is stably inherited; plasmid-free cells arise at the rate of 1 in 10^4 per generation.[129] It achieves this using two mechanisms: (1) by partly overcoming the strong maternal bias in plasmid transmission, and (2) by amplification to correct fluctuations in copy number caused by inefficient transmission.

Efficient segregation depends on having the *STB* locus *in cis* and the *REP1* and *REP2* gene products.[211] Amplification overcomes the host regulation which restricts each replication origin to one initiation per cell cycle; it appears to depend on the inverted repeat sequences and the *FLP* gene product. According to the model proposed by Futcher,[128] FLP promotes recombination between replicated and unreplicated DNA so that inversion occurs and two replication forks can follow each other around the circle. Replication terminates after a second recombination, and further recombination generates multiple 2μ monomers.

The simplest 2μ vectors contain the 2μ *ORI-STB*, a yeast selectable marker, and bacterial plasmid sequences (e.g. pWYG4, Figure 1), and are used in a $2\mu^+$ host strain which supplies REP1 and REP2 proteins.[211] *ORI-STB* expression vectors are the most convenient to use routinely in the laboratory

due to their small size and ease of manipulation. They are tenfold more stable than *ARS* plasmids, being lost in 1 to 3% of cells per generation in non-selective conditions, and are present in 10 to 40 copies per cell. In 2μ-free cells such plasmids behave as *ARS* vectors. Commonly-used *ORI-STB* vectors contain a 2·2 kb *Eco*RI fragment or a 2·1 kb *Hin*dIII fragment from the B form of 2μ, each having one inverted repeat. In order to limit recombination with 2μ, the inverted repeat can be removed, but it is important not to remove adjacent *STB*-distal sequences since these appear to have an important role in protecting *STB* from transcriptional inactivation.[266] It should be noted that shuttle vectors containing inverted repeats will exist as a variety of recombinants with the native 2μ.[139] In addition, there appears to be some competition between exogenous 2μ vectors and native 2μ such that the copy number of both is depressed.[130]

More complex 2μ-based shuttle vectors contain the *REP1* and *REP2* genes in addition to *ORI-STB* and can therefore be used in 2μ-free host strains.[8] They are more cumbersome than *ORI-STB* vectors but stabler and more suitable for scale-up. Many examples of this type of vector are disrupted in *D* (e.g. pJDB248), and some in *FLP* (e.g. pJDB219) so that they cannot flip or amplify in 2μ-free cells. Nevertheless *FLP*⁻ plasmids can reach high copy numbers in 2μ-free cells, presumably through asymmetric segregation. In $2\mu^+$ strains they can amplify independently if they have two inverted repeats, or following integration into 2μ if they have only one repeat. Recently, vectors have been developed which have all functional regions of 2μ intact, by insertion of the foreign DNA at the unique *Sna*BI site between *ORI* and *STB*.[32] These are highly stable, but still 20- to 80-fold less stable than native 2μ, possibly due to low-level transcription through *STB*. In future similar vectors should find wide use in foreign gene expression.

Vectors free of bacterial DNA may be advantageous in foreign gene expression in relation to food and drug regulatory authorities. They can be made in one of two ways: (1) by targetted integration of an expression cassette into native 2μ, or (2) by use of a shuttle vector which can remove bacterial sequences *in vivo* by excisional recombination. Using the latter approach, Chinery and Hinchcliffe[67] constructed 'disintegration vectors' which used the FLP/FRT system to excise bacterial DNA inserted at the *Xba*I site of one of the inverted repeats. Vectors with inserts at the unique *Pst*I site in *D* or the *Sna*BI site between *STB* and *ORI* were extremely stable, though it is not clear whether stability would be retained upon insertion of a high-level expression cassette.

A number of ultra-high-copy number vectors (e.g. pWYG7L, Figure 1) are based on pJDB219 which contains the entire 2μ B form cloned in the bacterial plasmid pMB9 with disruption of *FLP*.[24] The selectable marker is *LEU2*-d whose use results in very high copy numbers (200–400 copies per haploid genome); the fraction of cells with the highest plasmid copy number are constantly selected, resulting in reduced growth rate. Selective growth or use of other markers gives a more normal copy number of about 50 per cell.[109] pJDB219 is best used in 2μ-free cells since it can undergo FLP-mediated recombination with resident 2μ, leading to loss of the foreign DNA but retention of the *LEU2*-d marker.[98] In 2μ-free cells pJDB219 is very stable due to its high copy number, making it suitable for large-scale culture.[130,397] *FLP*⁺ versions of pJDB219, e.g. pXY, have greater stability in non-selective medium.[130] Since the entire sequence of pMB9 has not been determined, it may be more convenient to use a variant of pJDB219 based on pBR322, e.g. pC1/1.[385]

Vectors can have very high copy number even in non-selective conditions if extra FLP recombinase is supplied. For example, induction of FLP from a single integrated copy of the gene under control of the *GAL1* promoter leads to a shift in plasmid copy number from <50 to 200–400.[8] Alternatively, the autoselective high-copy *URA3*-d marker can be used in a *fur1* host strain.[237]

Regulated copy number vectors

Foreign gene expression could be regulated by inducing an increase in vector copy number. Two types of yeast episomal vectors with regulated copy number have been described: (1) vectors with regulatable centromeres, and (2) 2μ vectors in cells with inducible FLP (see above). The first type depends on the observation that *CEN* elements can be inactivated by transcription. Chlebowicz-Sledziewska and Sledziewski[69] constructed vectors containing the glucose-repressible *ADH2* promoter adjacent to *CEN3* and either an *ARS* or 2μ *STB-ORI*. In the *ARS* vectors copy number could be increased from 1–2 to 5–10 by a switch from glucose to ethanol as the carbon source. In the *ORI-STB* vectors copy number could be increased from 1–2 to about 100 and the vector was very stable. Such vectors could be used to increase the degree of regulation in expressing toxic proteins.

EGRATING VECTORS

vectors

ıromosomal integration offers a more stable native to episomal maintenance of foreign A. In *Saccharomyces* integration normally .rs by homologous recombination.[278] Integrat- 'ectors (YIp) contain yeast chromosomal DNA .rget integration, as well as a selectable marker bacterial replicon. Vectors are usually digested unique restriction site in the homologous DNA ıis promotes high efficiency transformation and :ts integration. Such single cross-over inte- ion results in a duplication of the chromosomal :t sequence, so that the vector can subsequently · out' by excisional recombination. Neverthe- the integrants are quite stable, the typical rate ector loss being <1% per generation in the nce of selection.[168]

ɔr convenience vector integration can be tar- :d to the chromosomal mutant allele of the :tion marker used. However, continued selec- of the resulting transformants is ineffective, : the duplicated DNA can be excised and a -type marker retained. In contrast, continued :tion is effective where integration is targetted vhere.

'hen high DNA concentrations of integrating ors are used in transformations, tandem multi- / inserts can result, presumably due to repeated mbination events.[277] Multi-copy integrants are :ively stable and have been used, for example, in : dosage studies.[57]

ısplacement

n alternative type of integration, transplace- .t, makes use of double homologous recombi- on to replace yeast chromosomal DNA, resulting stable structure without duplications.[313] Where ıble single-copy transformant is required this is method of choice. Transplacement vectors con- the exogenous DNA and selection marker ked by yeast DNA homologous to 5' and 3' ons of the chromosomal DNA to be replaced. ır to transformation the vector is digested with riction enzymes which liberate the transplacing ment with 5' and 3' homologous ends. The fre- ncy of transformation is low so that the sphaero- t method is usually used, and the chromosomal cture of the transformants must be checked notypically and by Southern blot analysis.

Integration into reiterated DNA

A number of strategies based on integration into reiterated chromosomal DNA have been used to generate stable multi-copy integrants. At present the best results in terms of copy number and expression appear to be using integration into the ribosomal DNA (rDNA) cluster. The rDNA cluster consists of about 140 tandem repeats of a 9·1 kb unit on chromosome XII. Lopes *et al.*[238,239] have constructed an integrating vector, pMIRY2, containing a portion of the rDNA unit and the *LEU2*-d marker. Transformation with pMIRY2 digested at *Sma*I or *Hpa*I gave Leu^+ transformants with 100–200 copies integrated at a non-transcribed spacer of the rDNA locus. Use of the *LEU2*-d or other promoter-defective markers was important for isolation of high copy integrants. The transformants were highly stable, 80–100% of the integrated copies being retained after 70 generations, and the levels of foreign protein produced using the *PGK* promoter were as high as from 2μ vectors. This approach could also be used as an alternative to episomal vectors in species where none has been found.

Another reiterated DNA that can be used as a target for integration is the transposable element *Ty* which is present in 30–40 copies per genome in most *Saccharomyces* strains. Kingsman *et al.*[216] described the use of a transplacement vector targetted to replace *Ty*, whose copy number could be amplified using the *LEU2*-d selection marker. Levels of interferon produced from such amplified transformants were several times higher than from single-copy *ARS/CEN* vectors but almost ten-fold less than with 2μ vectors. Jacobs *et al.*[193] used similar vectors in order to co-express the different forms of hepatitis B surface antigen (HBsAg). They obtained transformants containing from one to several copies of the vector without the need for amplification. The multi-copy transformants consisted mainly of the transplacing DNA at a single *Ty1* locus and arose by an unexplained mechanism. In order to co-express the different forms of HBsAg in the desired ratio, **a** and α strains were transformed with each vector, multi-copy integrants selected, and diploids made. Stable diploids with a total of 10 copies were made but expression levels appeared to be low.

More recently Shuster *et al.*[345] have used vectors that integrate by single cross-over into δ elements, which exist either alone or as part of *Ty* throughout the *S.cerevisiae* genome. They constructed a vector expressing the *E.coli lacZ* gene with the *LEU2* and *CUP1* markers. Leu^+ transformants were selected

following transformation with vector digested by *Xho*I, which cuts in the δ element within the *LEU2* marker fragment. These were then selected for copper-resistance to isolate multi-copy integrants which yielded up to ten-fold the β-galactosidase level of single-copy strains. Integration into δ, coupled with crossing of haploid integrants, has been used to generate a 20-copy strain for efficient secretion of nerve growth factor.[322]

Transposition vectors

A different approach to multi-copy integration is the use of *Ty* transposition vectors analogous to retroviral vectors for mammalian cells. *Ty* transposes *via* a full-length transcript which is encapsidated into virus-like particles and reverse transcribed to DNA, which can then integrate at multiple sites. In transposition vectors a regulated promoter, e.g. *GAL1*, is used in place of the *Ty* δ promoter to generate a transcript encompassing the foreign gene and selectable marker. Transcription termination signals must be removed from the marker gene for the full-length transcript to be produced. The whole unit is placed on an episomal vector for the initial transformation, but can be lost following induction of transposition. Boeke *et al.*[38] obtained relatively low copy number integrants (1–10) by this method, but it may prove feasible to use the *LEU2*-d gene for amplification. Although this method is not fully developed it could be useful in a variety of yeasts, since *Ty* encodes all the functions required for transposition.

TRANSCRIPTIONAL PROMOTERS AND TERMINATORS

Foreign versus *yeast promoters*

The expression of foreign genes in yeast was examined as soon as transformation procedures became available. The first study was of the rabbit β-globin gene which was found to give rise to aberrant transcripts in which the introns were not spliced.[25] In a few cases the foreign transcript was correctly initiated, e.g. with zein,[228] but in general foreign transcriptional promoters were found to give aberrant initiation, e.g. *Drosophila ADE8*,[161] or were totally inactive, e.g. herpes simplex virus thymidine kinase.[217] Thus for efficient transcription of foreign genes the use of yeast promoters with cDNAs was soon found to be essential. The first published example was the use of a 1500 bp fragment 5' of the *ADH1* gene for efficient intracellular expression of leukocyte α-interferon.[172]

Yeast mRNA promoters consist of at least three elements which regulate the efficiency and accuracy of initiation of transcription:[369] upstream activation sequences (UASs), TATA elements, and initiator elements. Many also contain elements involved in repression of transcription. UASs, which have some similarities to mammalian enhancers, determine the activity and regulation of the promoter through specific binding to transcriptional activators (e.g. *GAL4* and *GCN4*), and act at variable distances 5' to the initiation site. Some UASs have been mapped to short regions of DNA, e.g. the *GAL1-GAL10* UAS to a 108 bp intergenic region containing four short sequences of dyad symmetry. These sequences (17–21 bp) are necessary and sufficient for binding of the *GAL4 trans*-activator and for galactose-regulation, and act synergistically. UASs of some constitutively-expressed genes contain poly(dA-dT) tracts which probably activate transcription by affecting nucleosome structure.[369] TATA elements (consensus TATAA) are found 40 to 120 bp upstream of the initiation site, in contrast to the more rigid distance of 25 to 30 bp in higher eukaryotes, and provide a window within which initiation can occur.[369] The initiator element, which is poorly defined, directs mRNA initiation at closely adjacent sites. Yeast promoters may be highly complex, extending over 500 bp, containing multiple UASs and negative regulatory sites, and multiple TATA elements associated with different initiation sites.[369]

Most promoters are regulated to some extent, but the most powerful, glycolytic promoters are poorly regulated. This makes them undesirable for use in large-scale culture, where there is more opportunity for the selection of non-expressing cells, and unsuitable for expressing toxic proteins. In such cases it is preferable to use a tightly-regulated promoter so that the growth stage can be separated from the expression stage. Despite a severe limitation in efficiency with multiple copies, *GAL1* has been the most commonly-used regulated promoter. However, there is now a large variety of native or engineered promoters (Table 3); the right choice is critical for any one application, especially where a process is to be scaled-up.

Glycolytic promoters

The first promoters used were from genes encoding abundant glycolytic enzymes, e.g. alcohol dehydrogenase I (*ADH1*),[172] phosphoglycerate

Table 2. *S.cerevisiae* vector systems.

Vector	Yeast sequences	Transformation frequency[a]	Copy no. /cell	Mitotic instability[b]	Reference

kinase (*PGK*),[173,383] or glyceraldehyde-3-phosphate dehydrogenase (*GAP*).[177] These were at first thought to be constitutive but were later found to be induced by addition of glucose, e.g. expression of α-interferon using the *PGK* promoter was induced 20- to 30-fold by addition of glucose to a culture grown on acetate as carbon-source.[383] Glycolytic promoters are the most powerful of *S.cerevisiae*, for example *PGK* mRNA accumulates to 5% of total. Despite their poor induction ratio, *ADH1*, *PGK* and *GAP* vectors have been used extensively in the laboratory, and in some cases industrially.[250]

The *PGK* promoter has been studied in some detail: it extends over 500 bp, contains a complex UAS at -473 to-422 relative to the initiation site, a heat shock regulatory element, and other features contributing to accurate and efficient initiation.[215] In contrast, less is known about other glycolytic promoters, such as *GAP*. There are three *GAP* genes, of which *GAP491* or *TDH3* is the most highly-expressed and whose promoter has been used successfully to express a number of proteins.[311] The full-length promoter extends over approx. 700 bp,[33] but there have been a number of reports of smaller fragments having full promoter activity, e.g. a 198 bp fragment.[169] However, it appears that the activity of shorter *GAP491* promoters is dependent on bacterial vector sequences.[311]

Galactose-regulated promoters

The most powerful tightly-regulated promoters of *S.cerevisiae* are those of the galactose-regulated genes *GAL1*, *GAL7*, and *GAL10*, involved in metabolizing galactose. Galactose-regulation in yeast is now extremely well-studied and has become a key model system for eukaryotic transcriptional regulation (reviewed in reference 201). Many genes are involved in regulation of *GAL* promoters but the central interaction is between the *trans*-activator encoded by *GAL4*, the repressor encoded by *GAL80*, and the *GAL* UAS (Figure 4). Binding of GAL4 protein to the UAS is necessary for induction; GAL80 protein binds GAL4 and acts as a repressor unless galactose is added. The regions of GAL4 protein that bind GAL80 and the UAS have been defined, as have the structural features of the different *GAL* promoters.

GAL1, *GAL7* and *GAL10* mRNAs are rapidly induced > 1000-fold to approx. 1% of total mRNA on addition of galactose.[363] The promoters are

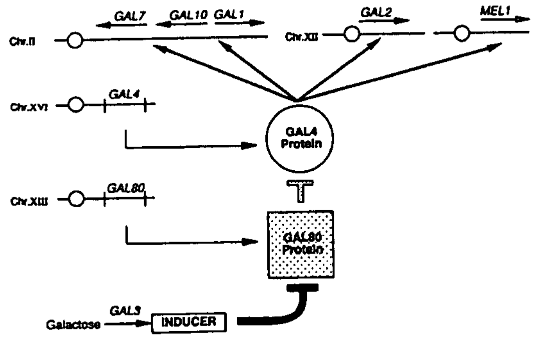

Figure 4. Galactose regulation in yeast. The genes involved in regulation and metabolism and their chromosomal location are shown. Stimulation is indicated by bold lines with arrows and inhibition by lines with bars.

ongly repressed by glucose, so that in glucose- ɔwn cultures maximal induction can only be hieved following depletion of glucose. Galactose- luctions can be carried out in one of three ways: by growing the culture on a non-repressing, non- lucing ('neutral') sugar, when very rapid induc- n follows addition of galactose; (2) by growing culture in glucose medium but removing the ıcose by centrifugation and washing the cells fore resuspension in galactose medium (this leads a lag of 3 to 5 h in induction[1]); and (3) by growing cells in medium containing both glucose and lactose, when the glucose is preferentially metab- ized before galactose-induction can occur. The st two methods are frequently used for small-scale it are impractical in large-scale inductions. It ould be noted that many commonly-used strains ive mutations in the galactose permease gene *AL2*) and are not inducible.

The large background of knowledge of galactose- gulation offers the possibility of manipulating the stem in a number of ways in order to improve its aracteristics for protein production. Three types manipulations that have been carried out are: (1) e over-expression of *trans*-activator; (2) the use of utations in the galactose-regulatory pathway or glucose-repression; and (3) the construction of imaeric galactose-regulated promoters.

GAL4 protein is present in one or two molecules r cell and, moreover, GAL80 repressor is in excess this and is galactose-inducible.[201] Therefore, even ith single-copy promoters, *GAL* transcription is mited by a shortage of GAL4 protein, though other factors also become limiting with multi-copy promoters.[13] With multi-copy expression vectors GAL4 limitation is exacerbated, for example β-galactosidase expression from a *GAL-lacZ* vector increases only two-fold in going from a single-copy to a 2μ vector.[413] Both with single and multi-copy vectors, two- to three-fold increases can be obtained in *gal80* strains, but expression then becomes constitutive.[413] Over-expression of *GAL4*, either by insertion of the gene into the multi-copy expression vector, or by use of a single-copy integrating *ADH1-GAL4* expression vector, increases product levels 2- to 3-fold, but again at the price of losing tight regulation.[13,158] Schultz *et al.*[334] used an integrated *GAL10-GAL4* expression vector in order to over-produce GAL4 protein in a galactose-regulated manner. Transcription from the target expression vector, encoding Epstein-Barr virus (EBV) gp350, was increased 5-fold. We have tested a similar system which used an integrated *ADH2-GAL4* expression vector in order to over-produce GAL4 protein. This system alters the regulation of *GAL* expression vectors so that they are induced by glucose-depletion. Using a constitutive *GAL4* gene, i.e. one that does not interact with GAL80 repressor, it was possible to increase levels of β-galactosidase produced from a multi-copy *GAL1* vector by 2- to 4-fold (M.A.R. and J.J.C., unpublished results).

In order to facilitate galactose-induction of glucose-grown cultures, the use of mutants defective in either global or *GAL*-specific glucose-repression has been examined. In *reg1-1* mutants efficient galactose-induction occurs with galactose to glucose

ratios of 5:1.[248] Hovland *et al.*[181] used a novel selection procedure to isolate glucose-resistant mutants, and found a *reg1* mutant (*reg1-501*) in which efficient induction occurred even with galactose/glucose ratios of 1/100. A *gal1 reg1-501* strain was made which cannot metabolize galactose so that very low levels of galactose (e.g. 0·2%) could be used, in the presence of excess glucose, for efficient induction.[181]

In an attempt to combine the high activity of glycolytic promoters with the tight regulation of *GAL* promoters, hybrid promoters have been constructed where a glycolytic UAS is replaced by a *GAL* UAS. However, the published results do not suggest that these hybrids are more efficient than *GAL* promoters. Bitter and Egan[35] have described the use of a *GAP/GAL* UAS hybrid for the expression of γ-interferon, which is toxic to yeast cells. Insertion of a 55 bp *GAL1-GAL10* UAS fragment between the *GAP* UAS and TATA element conferred galactose-regulation to the promoter. Product levels were significantly higher than with the native *GAP* promoter, due largely to a dramatically increased vector copy number, from 1 to 20–50 per cell. A similar type of hybrid promoter (*PAL*) has been constructed, by replacing the *PGK* UAS with a *GAL* UAS, and used for regulated production of α-interferon and human serum albumin.[77] However, no comparison of the efficiency of *GAL* and *PAL* promoters has been published; it would be expected that all *GAL*-UAS hybrid promoters would be severely limited by GAL4 protein.

Phosphate-regulated promoters

The promoter of the acid phosphatase gene, *PHO5*, is regulated by inorganic phosphate concentration and has been used extensively for foreign gene expression.[169] In one of the earliest studies, a 1·4 kb *PHO5* DNA fragment was used to drive production of α-interferon, which was induced 200-fold by switching to low-phosphate medium.[223] More recently, the structural features and regulation of the *PHO5* promoter have been studied in detail (reviewed in reference 394). The promoter, encompassing about 400 bp of DNA, contains two UASs which are necessary and sufficient for regulation. These contain 19 bp dyad sequences which bind the PHO4 *trans*-activator.

Since the *PHO5* promoter is not very strong, attempts have been made to use the *PHO5* UAS to confer regulation to glycolytic promoters. Hinnen *et al.*[169] constructed a series of *GAP/PHO5* UAS hybrids and tested them in expression vectors for eglin C. Some hybrid promoters yielded up to twice the amount of product as *GAP*, but the induction ratio was 2- to 5-fold compared to 40-fold for *PHO5*. Since no copy number data were available one cannot make conclusions about relative promoter strength.

Kramer *et al.*[223] constructed a host strain temperature-sensitive in the PHO4 *trans*-activator and defective in the PHO80 repressor (*pho4^ts pho80*) to achieve phosphate-independent induction of the *PHO5* promoter regulated by temperature. On lowering the temperature from 35°C to 23°C a 50-fold induction of α-interferon was achieved, but the absolute level was only one tenth that in wild-type induced cells.

Glucose-repressible promoters

Glucose-repression is a global system regulating the expression of a number of genes, including sugar fermentation genes, by the availability of glucose. Yeasts preferentially utilize sugars such as glucose that enter the glycolytic pathway directly. Genes involved in sucrose or galactose metabolism are transcriptionally repressed by glucose. Typical examples of promoters regulated primarily by glucose-repression are those of the *ADH2*, *SUC2* and *CYC1* genes, encoding alcohol dehydrogenase II, invertase and iso-1-cytochrome c, respectively.

The *ADH2* promoter is both powerful and tightly regulated and has been used for foreign gene expression.[291] Since it is repressed over 100-fold by glucose, it can be used for efficient expression of toxic proteins, e.g. insulin-like growth factor I (IGF-I).[343] Deletion analysis has identified a 260 bp region 5' to the initiation site which contains two UASs sufficient for full promoter activity and regulation.[26] UAS1 is a 22 bp inverted repeat which binds the ADR1 *trans*-activator.[105] We have used the 260 bp region, which is readily assembled from synthetic oligonucleotides, in efficient expression vectors (M.A.R. and J.J.C., unpublished results).

In order to maintain repression of *ADH2*, cells must be grown in excess glucose (e.g. 8%) until induction, which is effected by changing to fresh medium containing a non-fermentable carbon source, e.g. ethanol, glycerol, raffinose, etc. Alternatively, *ADH2* can be induced by culturing initially in a lower concentration of glucose (e.g. 1%) which is gradually depleted.[291] Glucose-repressible systems have a potentially serious disadvantage in industrial fermentations: it is difficult to maintain tight glucose-repression under conditions of glucose-limitation, which are required to achieve high cell density.

Irani *et al.*[187] showed that transcriptional factors, including the *ADR1 trans*-activator, became limiting for *ADH2* transcription from multi-copy plasmids. Over-expression of *ADR1* leads to loss of regulation, but *ADH2*-regulated over-expression of *ADR1*, from a single-copy integrating vector, has been used to increase the efficiency of *ADH2* expression systems without loss of regulation.[291] In this way it has been possible to increase expression of β-galactosidase from a single-copy *ADH2-lacZ* vector by 4- to 10-fold. The system usually results in about a 3-fold increase in yield for intracellular proteins and is used for commercial production (J. Shuster, personal communication).

Hybrid glycolytic/*ADH2* promoters have been constructed by transplanting the *ADH2* UAS into *GAP* proximal promoter sequences. Cousens *et al.*[78] fused the *ADH2* UAS containing the 22 bp dyad 320 bp upstream of the *GAP* TATA element, and were able to achieve tightly regulated production of a superoxide dismutase (SOD)-proinsulin fusion to >15% t.c.p. However, no critical comparison of the strength of the *ADH2*, *GAP*, and hybrid promoters has been published.

Other regulated promoter systems

A few other regulated promoter systems are worthy of comment here: these are of interest because their induction is independent of culture nutrients and can therefore be controlled without otherwise perturbing the culture.

A temperature-regulated system based on mating type control has been used by a number of groups. Mutations in the *SIR* genes de-repress the silent mating-type loci, so that a or α-specific genes are not expressed. Repression of the *MFα1* promoter is mediated by the *MATα2* repressor which binds a 31 bp operator sequence. Brake *et al.*[42] first reported the use of a *MATa sir3*ts strain for secretion of hEGF using the α-factor (*MFα1*) promoter. Switching from the non-permissive (35°C) to the permissive (25°C) temperature led to an induction in secreted hEGF from 10 ng/l to 4 mg/l. The α2 operator has been transferred to the strong *ADH2* and *TPI* (triose phosphate isomerase) promoters and shown to confer temperature regulation in a *MATa sir3*ts strain. Sledziewski *et al.*[352] inserted up to four operators between the UAS and TATA elements of the *TPI* promoter and were able to obtain tight regulation (>50-fold induction of β-galactosidase) and full activity. Inexplicably, the hybrid *ADH2* promoters were not tightly temperature-regulated. The system appears amenable to fine-tuning by use of intermediate induction temperatures. A similar system has been developed by insertion of two α2 operators in the *PGK* promoter, achieving a >100-fold induction ratio without any reduction in activity.[398]

A novel type of promoter system uses the ability of mammalian steroid hormone receptors to function as transcriptional activators in yeast. Schena *et al.*[332] constructed a *CYC1* expression vector under the control of three tandem 26 bp glucocorticoid response elements fused upstream of the promoter. In yeast cells also expressing the glucocorticoid receptor, a CAT reporter gene could be induced 50- to 100-fold to high levels by addition of deoxycorticosterone (DOC). The degree of induction was titratable over 1 nM to 10 μM-DOC and was very rapid ($t_{1/2}$ of 7 to 9 mins). A similar system has been developed using a hybrid *PGK* promoter containing androgen response elements.[295] Addition of increasing amounts of dihydrotestosterone induced increasing amounts of β-galactosidase reporter over a several hundred-fold range, and the range could be extended to 1400-fold by varying the copy number of the receptor or reporter genes. In conclusion, steroid-regulated systems appear to be powerful and tightly-controlled, and could be used in yeasts lacking promoters with these qualities (e.g. *K.lactis* and *S.pombe*).

The promoter of the *CUP1* gene, encoding copper metallothionein, has been used in expression vectors.[113] This promoter is tightly-regulated and independent of culture parameters. The concentration of Cu^{2+} ions for induction depends on the copper-resistance of the host strain from 0·01 mM (no *CUP1* gene) to 0·5 mM (>6 copies).

Selection of novel yeast promoters

A number of selection or screening methods have been used in order to identify new promoters from a genomic library.[147,326] Selection procedures can be devised for regulated promoters, e.g. the glucose-repressible promoters of the *GUT2* and *PRB1* genes which encode glycerol-3-phosphate dehydrogenase and vacuolar endoprotease B, respectively.[354,356]

Foreign promoters systems

Foreign promoters not recognized by yeast RNA polymerase can in principle be used provided the cognate RNA polymerase is co-expressed. The bacteriophage T7 RNA polymerase is highly active and has been used in a number of prokaryotic and

eukaryotic organisms. T7 RNA polymerase, ideally with an added nuclear targetting signal, can be expressed from a *GAL1* promoter and can efficiently transcribe DNA in yeast cells.[29,63] However the T7-induced *lacZ* mRNA is not translated in yeast, due either to absence of 5' caps and/or polyadenylation, or to a stable hairpin formed in the 5' region.[29] In animal cells a similar problem has been solved using the encephalomyocarditis virus leader to promote cap-independent translation,[108] but this appears to be inactive in yeast (C.A.S., unpublished results). If the translation problem were solved a yeast T7 system would be very powerful, since *GAL1*-driven expression of the polymerase would act as an amplification step.

Yeast terminators

Yeast transcriptional terminators are usually present in expression vectors for efficient mRNA 3' end formation. Terminators of prokaryotic or higher eukaryotic genes are not normally active in yeast, though there are exceptions such as the *Drosophila ADE8* gene.[161] Efficient termination is probably required for maximal expression: deletion of 'termination' sequences 3' of the *CYC1* gene resulted in longer mRNA and a dramatic reduction in mRNA level.[415]

Transcriptional termination of yeast mRNAs is less well understood than that in bacteria and in higher eukaryotes. Bacterial transcription terminates at the mature 3' end of the mRNA. In higher eukaryotes mRNA 3' end formation involves cleavage and polyadenylation, downstream of the signal AAUAAA, of precursor mRNAs that extend several hundred nucleotides beyond the coding region. Contrary to earlier ideas, it appears that yeast mRNAs follow the same pattern of termination, processing and polyadenylation of pre-mRNA as higher eukaryotes. However in yeast these processes are tightly coupled and occur within a shorter distance, near the 3' end of the gene.[52]

A number of consensus sequences have been implicated as part of the mRNA 'terminator', especially the tripartite sequence TAG..(T-rich)..TA(T)GT..(AT-rich)..TTT[416] and TTTTTATA.[160] The commonly found tripartite motif shows poor conservation and is tolerant of large sequence alterations, suggesting that a general feature such as high AT-content may be critical.[279] However this cannot be sufficient since terminators are frequently absent in AT-rich DNA, and can be unidirectional, implying some sequence specificity. More recent evidence suggests that a variety of different signals, unidirectional and bidirectional, are used in yeast.[188]

Terminators from a number of genes have been used in expression vectors, e.g. *TRP1*,[172] *ADH1*,[385] *GAP*,[310] *MF1*,[42] etc. In order to simplify vector construction, a terminator from 2μ[371] can be used, e.g. the *FLP*[173] (pWYG7L, Figure 1) or *D* gene terminator[304] (pWYG4, Figure 1).

FACTORS AFFECTING INTRACELLULAR EXPRESSION

Initiation of transcription

Gene expression is most frequently regulated at the level of transcription, and it is generally assumed that the steady-state mRNA level is a primary determinant of the final yield of a foreign protein. The mRNA level is determined both by the rate of initiation and the rate of turnover.

In most cases the yield of a foreign protein expressed using a yeast promoter has been much lower than the yield of the homologous protein using the same promoter. Using the *PGK* promoter on a multi-copy vector several proteins accumulate to 1 to 2% t.c.p., whereas with the entire *PGK* gene phosphoglycerate kinase accumulates to over 50%.[62,254] These levels reflect to a large extent the lower amounts of the foreign *versus PGK* transcripts for as many as 20 genes,[62] although there appear to be exceptions.[154] It was suggested that the reduced levels were due to shorter $t_{1/2}$s for the foreign transcripts, but Mellor *et al.*[253] showed that α-interferon mRNA was not unstable but was initiated at a six-fold lower rate. Addition of downstream *PGK* sequences restored the mRNA level to that for *PGK* mRNA, suggesting the presence of a downstream activation sequence (DAS), localized to the first 79 codons, required for maximal transcription. Indirect evidence for a DAS has also been found with the pyruvate kinase (*PYK*) gene.[292] Attachment of the *lacZ* gene to the *PYK* promoter resulted in a 30-fold drop in mRNA molarity, whereas its $t_{1/2}$ decreased only two-fold, consistent with a 15-fold drop in the initiation rate. The putative *PYK* DAS is active in single- and multi-copy vectors, has been localized to nt 500 to 800 relative to the initiating ATG, and appears to be able to functionally replace the *PGK* DAS (A. Brown, personal communication). Evidence for DASs has also been found in the lipoamide dehydrogenase gene,[414] and in *Ty2* DNA.[232]

milar problem in *P. pastoris* with two bacterial genes (63% and 67% AT) was solved by increasing GC-content (K. Sreekrishna, onal communication).

ince the evidence may now favour the existence)ASs in certain genes it is possible that they will found in many others. There may be some cir- nstantial evidence for this, e.g. multi-copy *GAL7* :s levels of uridyltransferase of >15% t.c.p.,[13] :reas foreign proteins rarely reach this level. It st be emphasized that many other factors could ount for these differences. If DASs are character- l, it may be possible to incorporate them into :tream promoter fragments in order to create re efficient expression vectors. Alternatively, if ,Ss prove to be strongly position-dependent, they ıld be placed within an intron which would be ised prior to translation. If neither of these ions work, then maximal transcription will only be ievable using fusion proteins, for example to PGK. \n alternative to all these approaches is to use a :erent yeast, such as *P.pastoris* which does not)ear to have the same problem.

Yeast expression vectors frequently give rise to merous unexpected transcripts arising from for- tous promoters in bacterial plasmid DNA.[245] It is t known whether they can affect foreign gene expression, but antisense transcripts through the foreign gene can be eliminated by using bidirectional terminators or by judicious juxtaposition with 2μ DNA (e.g. *FLP* terminator).

RNA elongation

The elongation of transcripts is not thought normally to affect the overall rate of transcription, but the yield of full-length transcripts could be affected by fortuitous sequences in foreign genes which cause pausing or termination. These could either act in the same way as natural yeast terminators or else by a different mechanism. We have found evidence of this in a remarkably high proportion of the genes we have examined, especially, but not exclusively, in those with unusually high AT-content. Though not widely recognized, this problem could be a very common reason for low yields or complete failure of foreign gene expression in yeast.

We have listed examples of lack of expression of AT-rich genes in Table 4. The presence of truncated mRNA has not been demonstrated in every case, but the clearest published example is in the expression

of the AT-rich *Clostridium tetani* DNA encoding tetanus toxin fragment C.[307] RNA was analysed from the native gene and from each of three versions of the gene containing progressively more synthetic DNA, starting from the 5' end (Figure 5). The transcript length increased through this series, with only the fully-synthetic gene giving full-length mRNA as the major species. All the short and full-length transcripts were discrete, abundant and polyadenylated. The 1·5 kb *C.tetani* DNA was shown to contain at least six fortuitous polyadenylation sites which were eliminated by increasing GC-content (from 29% to 47%). The partially-synthetic genes gave rise to low levels of run-off translation products, but efficient production of fragment C was only achieved with the fully-synthetic gene.

The problem with AT-rich genes means that analysis of genomes with high AT-contents (e.g. *Plasmodium falciparum* or *Dictyostelium discoideum*) by complementation in *S.cerevisiae* is possibly not worth pursuing as a general strategy. Such studies might be attempted in *S.pombe*, though recent work suggests that the two yeasts have a conserved mechanism for mRNA 3' end formation.[184] More worryingly, there is evidence of the same problem with genes having an average AT-content similar to that of yeast (60%). With the HIV-1 *env* gene, truncated mRNA was found in *P.pastoris* but not *S.cerevisiae*. Mutagenesis of a sequence resembling a polyadenylation consensus inactivated a major polyadenylation site but revealed several weak sites which were removed by increasing GC-content using chemical synthesis (C.A.S. and R.G. Buckholz, in preparation).

The frequency of the problem means that it would be desirable to be able to predict its occurrence, and to solve it without resorting to gene synthesis. Unfortunately it appears to be very difficult to identify polyadenylation sites by searching for consensus sequences, especially in AT-rich DNA. In the case of the fragment C gene, one of the short mRNAs could have been due to a single TTTTTATA sequence, but a number of tripartite motifs were found in regions with no polyadenylation sites.[307]

At present the only solution is to increase the GC-content of offending sections of genes by chemical synthesis. The success of more general solutions would depend on whether the problem is due to true premature termination or to uncoupled post-transcriptional processing. In the former case a foreign RNA polymerase which uses different termination signals, e.g. T7 RNA polymerase, might produce full-length mRNA. Unfortunately, the T7 system is not fully developed in yeast (see Transcriptional promoters and terminators). If the problem is one of post-transcriptional processing then it may be necessary to use an extranuclear expression vector, e.g. one based on the linear AT-rich plasmids of *K.lactis* which can also be propagated in *S. cerevisiae*, to segregate the transcripts from nuclear processing enzymes.[365]

RNA stability

The half-lives of yeast mRNAs range from 1 to 100 min and can therefore have a profound effect on the steady-state level (reviewed in reference 47). A careful study of 15 randomly-chosen mRNAs showed two populations, one with longer $t_{1/2}$s (40 to 100 min) and one with shorter $t_{1/2}$s (6 to 20 min).[47] Within each class there was an inverse relation between mRNA length and stability. However, there is some disagreement over this division into two classes.[162] The difference between stable and unstable mRNAs may be that the latter have destabilizing elements, since sequences from the short-lived *URA3* mRNA destabilize *PYK* mRNA.[48] A number of the unstable mRNAs have recently been found to encode ribosomal proteins (A. Brown, personal communication); the foreign *lacZ* mRNA has a $t_{1/2}$ of 27 min.[292]

Insertion of premature stop codons in *URA1*, *URA3* and *PGK* mRNAs has been shown to cause their destabilization, suggesting that ribosome attachment may contribute to mRNA stability.[175,241,283] However the same result was not observed for a *PYK* and *PYK-lacZ* mRNA,[292] suggesting a complex relationship between mRNA stability and translation. Santiago *et al.*[327] found no obvious correlation between ribosome loading and stability for ten different mRNAs.

There appear to be few examples of low mRNA stability being a primary factor in poor yields of foreign proteins. Due to the lack of knowledge of yeast mRNA degradation mechanisms it is impossible to predict whether a foreign mRNA will be stable, though we might expect long mRNAs to be somewhat less stable than short ones. AU-rich sequences in the 3'-ends of some mammalian mRNAs confer instability,[339] but it is not known whether they function in yeast. Where mRNA instability is diagnosed as a problem, overall yield might be improved by (i) using a more powerful promoter, (ii) using a promoter with more rapid induction kinetics, or (iii) chemically synthesizing the gene with altered codons or deleting the 3' untranslated

region[90a] in the hope that instability determinants will be removed.

Initiation of translation

Translational efficiency is thought to be controlled primarily by the rate of initiation. This is affected by the structure of the 5' untranslated leader of a mRNA, and there are examples of poor expression due to the presence of sub-optimal foreign 5' leaders. Using a multi-copy *GAP491* promoter vector to express hepatitis B core antigen (HBcAg) Kniskern *et al.*[218] found that the product accumulated to 0·05% of soluble cell protein when viral 5' and 3' sequences of about 100 nt were retained. Deletion of the 5' viral sequence raised the yield to 26%, while deletion of 5' and 3' viral sequences raised it to 41%, both without altering mRNA levels.

Initiation in eukaryotes is thought to follow a scanning mechanism whereby the 40S ribosomal subunit plus co-factors (eIF2, eIF3, eIF4C, Met-tRNA and GTP) bind the 5' cap of the mRNA then migrate down the untranslated leader scanning for the first AUG codon.[222] Any part of this process, which is affected by the structure of the leader and the AUG context, could limit the initiation rate. Yeast mRNA leaders have an average length of about 50 nt, are A-rich, have little secondary structure, and almost always use the first AUG for initiation (reviewed in reference 70). The length of the untranslated leader does not seem to be critical: although there is a 50% reduction in efficiency when the *PGK* leader is shortened from 45 to 21 nt, further shortening to 7 nt has no effect.[389] Insertion of long runs of Gs is very deleterious, however, causing a complete inhibition of translation; runs of Us have a partial effect possibly caused by interaction with the polyA tail.[390] The most significant single factor is secondary structure: hairpins of $\Delta G = -20$ kcal/mol can drastically inhibit translation of *HIS4* or *CYC1* mRNA in yeast cells,[11,71] in contrast to the much lower sensitivity of translation to leader secondary structure in mammalian cells.

The consensus sequence around the initiating AUG, A/YAA/UAA<u>AUG</u>UCU,[70] in yeast is different from that in higher eukaryotes (CACC<u>AUG</u>G). It has been speculated that the mammalian context reflects an interaction with the sequence GUGG in 18S rRNA. The prevalence of UCU as the second codon may reflect the preference for stabilizing amino acids according to the N-end rule (see below). Although there is a strong bias for A at-3, especially in highly-expressed genes, alteration of the AUG context of mRNAs in yeast has at most a 2- to 3-fold effect, in contrast to the much greater effect in mammalian cells.[11,71]

As a consequence of these considerations it is preferable to avoid the inclusion of foreign non-coding sequences in yeast expression vectors. However, where this is inconvenient it should be possible to predict whether a foreign 5' leader will be deleterious by examining the sequence for secondary structure or runs of Gs or Us. For example, analysis of the sequence 5' to the HBcAg gene, found by Kniskern *et al.*[218] to inhibit translation, shows a number of predicted secondary structures of up to $\Delta G = -35$ kcal/mol (M.A.R., unpublished results).

Translational elongation

Translational elongation is not thought to affect the yield or quality of polypeptide normally, but there is now some evidence that it can become limiting with very high mRNA levels. Codon usage is known to affect the elongation rate and therefore has to be considered as a *potential* factor affecting product yield. In the past it has been discounted on the basis that some genes containing many rare codons, e.g. *lacZ* or HBcAg, are expressed at high levels; however, these gene products are unusually stable and their yield does not reflect overall translational efficiency.

Despite the degeneracy of the genetic code, a non-random codon usage is found in most organisms: whilst the codon usage of most genes reflects the nucleotide composition of the genome, highly-expressed genes show a strong bias towards a subset of codons.[28,338] This 'major codon bias', which can vary greatly between organisms, is thought to be a growth optimization strategy such that only a subset of tRNAs and aminoacyl-tRNA synthetases is needed at high concentration for efficient translation of highly-expressed genes at fast growth rates.[227] Rare codons, for which the cognate tRNA is less abundant, are translated at a slower rate in *E.coli*,[282] but this will not normally affect the level of product from an mRNA since *initiation* is usually rate-limiting. A ribosome finishing translation of one mRNA molecule is most likely to initiate translation of a different mRNA species, unless the original species comprises a large proportion of total mRNA. Thus, the overall rate of translation of an mRNA is not usually affected by a slower elongation rate unless ribosomes become limiting, which would affect all transcripts in the cell.

In contrast to the normal situation, there is evi-ence that codon usage may affect both the yield and uality of a protein when a gene is transcribed to very igh levels. With very high levels of mRNA contain-ıg rare codons, aminoacyl-tRNAs may become miting, increasing the probability of amino acid ıisincorporations, and possibly causing ribosomes ɔ drop off. Indeed, a high misincorporation fre-uency has recently been observed in a foreign pro-ːin produced at very high levels in *E.coli*.[336] The ·resence of many very rare codons has been shown ɔ limit the production of tetanus toxin fragment C ı *E.coli*.[242] In yeast, Hoekema *et al.*[175] showed that ubstitution of a large proportion of preferred odons with rare codons in the 5' portion of the *PGK* ene caused a decrease in expression level. However, hese substitutions were made in the region contain-ıg a putative DAS,[253] possibly contributing to the ffect on expression levels. Translation of *lacZ* ıRNA, which contains a high proportion of rare odons, was shown to be limiting at high levels.[292] 'here was a decrease in ribosome loading, possibly ue to pausing and drop-off, on *lacZ* mRNA and on *'RP2* mRNA, which also has poor codon bias. ːecently, expression of an immunoglobulin kappa hain in yeast was shown to increase 50-fold, with-ut a change in mRNA levels, using a synthetic, odon-optimized gene.[220]

Thus the codon content of a foreign gene may ıfluence the yield of protein where the mRNA is ·roduced at very high levels. This may be more likely ɔ occur on growth in minimal medium, when the cell ·roduces a wide variety of biosynthetic enzymes, ncoded by genes containing rare codons.[338] The ffect on product quality has been difficult to measure ·ut requires further attention since it has important nplications for therapeutic proteins.[336] Proteins ontaining amino acid misincorporations are diffi-ult to separate and may affect the activity and ntigenicity of the product. Since small genes are ow frequently synthesized chemically they may ·e easily and perhaps profitably engineered to con-ıin optimal codons for high-level expression in east.

mRNA secondary structure, in addition to codon sage, may affect translational elongation. Baim *t al.*[10] showed that a mutation which introduced a .airpin loop ($\Delta G = -19{\cdot}6$ kcal/mol) near the 5' end ·f the coding region of *CYC1* mRNA reduced the mount of protein product five-fold. mRNA levels /ere unchanged and analysis of the distribution of *:YC1* mRNA on polysome gradients indicated that ranslation was affected.

Polypeptide folding

During or following translation, polypeptides must fold so as to adopt their functionally-active conformation. Since many denatured proteins can be refolded *in vitro*, it appears that the information for correct folding is contained in the primary poly-peptide structure.[140] However, folding comprises rate-limiting steps during which some molecules may aggregate, particularly at high rates of synthesis and at higher temperatures.[210] There is evidence that certain heat-shock proteins act as molecular chaperones in preventing the formation and accumulation of unfolded aggregates, while accelerating the folding reactions.[140]

Due to the intrinsic nature of polypeptide folding and the low specificity of chaperones, it is very unlikely that foreign cytosolic proteins will accumulate in yeast in non-native conformations, and indeed this is generally the case. When fragments of proteins or fusion proteins are expressed, however, normal folding domains may be perturbed resulting in an insoluble product. Nevertheless, fusion proteins that are insoluble in *E.coli* may frequently be soluble when expressed in yeast, e.g. fusions to β-galactosidase (J.J.C., unpublished results), glutathione-S-transferase (GST; M.A.R., unpublished results), and HBcAg.[23] Insoluble proteins can often be renatured *in vitro* though the techniques for this can be complex and unpredictable.[246]

In contrast to intracellular proteins, naturally-secreted proteins encounter an abnormal environment in the cytoplasm: disulphide bond formation is not favoured and glycosylation cannot occur. Though many secreted proteins are insoluble when expressed intracellularly, e.g. prochymosin,[146] human serum albumin,[294] HIV gp120,[19] some are soluble and biologically-active, e.g. α-interferon,[172] α_1-antitrypsin,[310] tumour necrosis factor,[359] Factor XIIIa.[300] Factor XIIIa is interesting in that it has nine Cys residues, none of which forms disulphide bonds.

In *E.coli*, foreign proteins are frequently insoluble but low temperature has been found to increase solubility in some cases.[331] This may be due to a decreased translation rate or to the fact that hydrophobic interactions, such as occur in aggregates, become less favourable. A dramatic increase in the yield of active, soluble protein has been reported on reducing the rate of induction in *E.coli*.[219] Low temperature or reduced induction rates may increase product solubility in yeast. For example, in the intracellular expression of the bacterial membrane protein pertactin, the proportion of the product that was soluble decreased from 100% to 10% as the expression level was increased from 0·1% to 10% t.c.p.[306]

Table 5. Effect of penultimate amino acid in determining mature N-terminus of intracellular proteins.

	Met removed	Met retained
No N^{α}-acetylation	Pro, Val, Cys	Ile, Leu, Met, Phe, Tyr, Trp, Lys, His, Arg, Gln
N^{α}-acetylation	Gly, Ala, Ser, Thr	Asp, Glu, Asn

Similar considerations apply to the assembly of foreign multimeric proteins. Examples of homo-polymeric assembly include the HBcAg[218] and HBsAg.[387] The latter is inserted into intracellular yeast membranes to form immunogenic 22 nm particles resembling those found in the serum of chronic HBV carriers. In early studies only a proportion of the HBsAg was found to be immunologically-active, and later work showed that mature particles only formed during extraction, when SH residues oxidized to form inter-chain S_2 bonds.[399] More recent work in *P.pastoris* showed that a much higher proportion of HBsAg was correctly folded when produced in a strain growing slowly during induction, suggesting rate-limiting folding steps related to growth rate.[81]

There are few published examples of heteromultimeric assembly in yeast, but a notable one is the co-expression of α and β-globin cDNAs to produce haemoglobin.[396] The yield of fully-assembled, soluble haemoglobin, which incorporated yeast haem, was 3 to 5% t.c.p. Another interesting example is in the simultaneous intracellular expression of heavy and light chains of an IgG directed against ADH I: these were able to assemble in the cytoplasm and partially block ADH I activity *in vivo*, despite the fact that the inter-chain S_2 bonds would not form.[56] Similarly, intracellular expression of a catalytic antibody Fab fragment yielded functional product at 0·1% t.c.p.[39]

Post-translational processing

Amino-terminal modifications of polypeptides are the commonest processing events and occur on most cytosolic proteins (reviewed in reference 209). Two types of events normally occur: removal of the N-terminal Met residue, catalysed by Met amino-peptidase (MAP), and acetylation of the N-terminal residue, catalysed by N^{α}-acetyltransferase (NAT). Both enzymes are associated with ribosomes and act on nascent polypeptides.

The specificities of yeast MAP and NAT (Table 5) have been determined by N-terminal amino acid analysis of mutant iso-1-cytochrome *c* or thaumatin polypeptides,[183,260] and more recently by studies of purified MAP.[60] The specificity of MAP is determined by the size of the penultimate residue. When this is has a radius of gyration of < 1·29 A (Gly, Ala, Ser, Cys, Thr, Pro and Val) the Met is removed, though with the larger residues Thr and Val there is only partial removal if they are followed by Pro. With other penultimate residues Met is retained. These rules appear to be reliable and highly conserved among eukaryotes, so mammalian proteins produced in yeast should have the normal N-terminal residue.

Recently it has been shown that fusions of proteins to the C-terminus of ubiquitin are rapidly processed *in vivo* when expressed in yeast, liberating the mature protein.[321,393] This approach is useful since it can be used to generate a protein with any desired N-terminus (apart from Pro), and appears to significantly increase the product yield in some cases.[101]

The factors governing N^{α}-acetylation are less clear. It appears that Met-Glu/Asp is sufficient for acetylation in eukaryotes.[260] N-terminal Gly, Ala, Ser, Thr and Met-Asn may also be acetylated, though effects of second and third residues make this less predictable.[209] However, there is evidence that the process is conserved among eukaryotes, so that proteins acetylated in mammalian cells might be expected to be acetylated in yeast cells.[156]

In most cases the structure of the N-terminus should not affect biological activity of a protein, but there may be exceptions. For example the response of haemoglobin to physiological modifiers involves the N-terminus, and correct processing of α and β-globins in yeast is therefore advantageous over expression in *E.coli*.[396] N^{α}-acetylation of melano-cyte-stimulating hormone and of β-endorphin is required for full biological activity (reviewed in reference 209).

A variety of other post-translational modifications which are often critical for biological activity appear to be conserved between yeast and higher eukaryotes. The phosphoproteins fos and c-myc are correctly phosphorylated in yeast.[258,325] Myristylation is a co-translational modification of N-terminal Gly important for the membrane targetting of certain proteins, e.g. G proteins, src tyrosine kinases, and retroviral gag proteins, and this also occurs in yeast.[195] Isoprenylation affects an important class of membrane proteins including G proteins and ras proteins:[330] the Cys of C-terminal Cys-X-X-X-CO_2H is isoprenylated, following which the three C-terminal residues are removed and the Cys-CO_2H is methyl-esterified. Mammalian proteins such as H-ras p21 are isoprenylated in yeast.

Stability of intracellular proteins

So far, processes affecting the rate of synthesis of proteins have been considered, but the ultimate yield is equally affected by the rate of degradation. In fact the few examples of very high level expression (>25% t.c.p.) in *S.cerevisiae* are of unusually stable proteins, e.g. SOD,[156] HBcAg,[218] and schistosomal GST.[237] This reflects a difficulty in achieving a very high rate of synthesis of foreign proteins in *S.cerevisiae*, probably at the level of transcription.

Very low yields are obtained with proteins which are naturally short-lived, such as myc,[258] or with some polypeptides which are naturally secreted, such as insulin[366] and hEGF.[385] In some cases fusion to a stable protein has given high-level accumulation in yeast, for example with a hybrid TAT-Ty particle,[40] a SOD-proinsulin fusion protein,[78] fusions to GST (M.A.R., unpublished results), and a variety of peptides fused to HBcAg.[23] Alternatively, secretion has been used to segregate the product from intracellular proteases. In the case of HBsAg particles containing the pre-S2 peptide, proteolytic cleavage occurred at a specific site and could be reduced by using a protease-deficient (*pep4*) strain or by mutation to remove the susceptible region.[190] Where these approaches fail, yields might logically be improved by the following measures: (i) using a more rapidly-induced promoter, (ii) using additional protease inhibitors to minimize degradation during extraction, (iii) inducing at lower temperature, (iv) harvesting cells in the exponential growth phase.

A number of different pathways of protein degradation exist and therefore there are multiple molecular determinants that confer instability (reviewed in reference 96). Unfortunately, we do not know all the determinants nor the relative importance of different pathways. Vacuolar degradation is responsible for non-selective bulk turnover of long-lived proteins (average $t_{1/2}$ approx. 160 h), whereas short-lived proteins ($t_{1/2}$ <2·5 h) are degraded in the cytosol by an ATP-dependent pathway involving ubiquitin.

A number of proteases, activated by the *PEP4* and *PRB1* gene products, are responsible for yeast vacuolar degradation.[170] Mutations in both genes dramatically reduce cellular proteolysis and should also reduce the risk of proteolysis during extraction. *pep4* mutants are widely used, but do not normally appear to offer an advantage in product yield. Indeed a general reduction in protein turnover rate would not be expected to increase the *relative* accumulation of a foreign protein, though it might increase the total protein yield. Vacuolar proteolysis is affected by culture conditions and increases several-fold during N- or C-starvation or in stationary phase.[170]

In the ubiquitin pathway proteins are marked by covalent attachment of ubiquitin, a 76-residue polypeptide, and become substrates for rapid degradation by a cytosolic ATP-dependent proteasome.[96] In addition to short-lived proteins, damaged or denatured proteins conjugate ubiquitin more efficiently and are targetted for degradation.

Varshavsky and co-workers have identified one component of ubiquitin recognition as the N-terminal amino acid (the N-end rule pathway; reviewed in reference 393). The N-end rule was uncovered by the production of β-galactosidase variants containing different N-terminal residues, which were generated by the expression and spontaneous processing of ubiquitin-β-galactosidase fusions; the $t_{1/2}$s of these variants ranged from 2 min to > 20 h. The N-end rule degradation signal actually comprises two determinants: a destabilizing N-terminal amino acid and a proximal internal Lys. Destabilizing residues are classified as Type I (positively charged: Arg, Lys, His), Type II (bulky hydrophobic: Phe, Tyr, Trp, Leu, and Ile in yeast), and Type III (small uncharged: Ala, Ser, Thr), the latter are not destabilizing in yeast. Additionally, the residues Asp and Glu are secondary destabilizing residues since they are substrates for post-translational addition of Arg; Asn and Gln are tertiary destabilizing residues since they can be deamidated *in vivo*. Recognition of a destabilizing N-terminus results in multiple ubiquitination of the internal Lys residue which is the prelude to degradation.

In agreement with the N-end rule, almost all cytosolic proteins with known N-termini have stabilizing amino acids. This might be expected from the striking inverse correlation between the N-end rule and N-termini that are generated by MAP. (In contrast most secreted proteins have destabilizing N-termini.) However, recent data suggest that the N-end rule is only one component, possibly a minor one, of the ubiquitin pathway. Mutations in the yeast gene (*UBR1*) for the Type I and II recognition component dramatically stabilized Arg-galactosidase but did not affect either bulk proteolysis or ubiquitin-dependent degradation.[20] A similar result was obtained using inhibitors of Type I (Arg-Ala) or Type II (Leu-OMe) recognition *in vivo*, resulting in a ten-fold stabilization of Arg- or Leu-galactosidase, respectively, and > 50-fold increases in accumulated protein.[12] Therefore other, undefined, signals are more important in the ubiquitin pathway.

Another proposed signal for rapid degradation is a variable sequence rich in Pro, Glu, Ser, and Thr (PEST) found in the majority of short-lived proteins.[301] Recently, addition of PEST sequences has been shown to destabilize DHFR.[235] It is not clear whether degradation of proteins containing PEST sequences involves the ubiquitin pathway.

SECRETION OF FOREIGN PROTEINS

Introduction

A wide variety of heterologous proteins have been secreted from yeast and this approach offers certain advantages over intracellular production. Although *S.cerevisiae* secretes only 0·5% of its own proteins, this level can be increased several-fold so that a secreted foreign protein can be almost pure in the medium. Many pharmacologically-important proteins are naturally secreted and can often only adopt their correct conformation by folding within the secretory pathway. As a consequence, intracellular expression is often unsuitable since the product may be insoluble and may also have an incorrect N-terminus, although this can be overcome by fusion to ubiquitin (see 'Factors affecting intracellular expression'). Thus secretion is used mainly for the production of correctly-folded, naturally-secreted proteins, but there are, in addition, other instances when secretion may be preferable. For example, some proteins are unstable or toxic when cytoplasmically-expressed and these problems may be circumvented by secretion.

As in higher eukaryotes, protein secretion in yeast is directed by an amino-terminal signal sequence which mediates co-translational translocation into the endoplasmic reticulum (ER). The signal peptide is removed by a signal peptidase. In the lumen of the ER

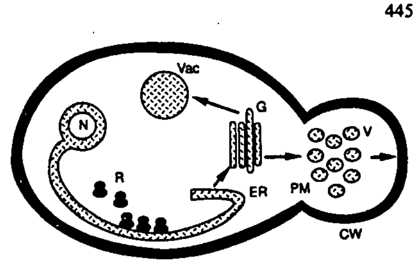

Figure 6. The yeast secretory pathway. Arrows indicate the route taken by proteins through the secretory pathway to either the vacuole or the plasma membrane. N, nucleus; R, ribosomes; ER, endoplasmic reticulum; G, Golgi; Vac, vacuole; V, secretory vesicles; PM, plasma membrane; CW, cell wall.

asparagine-linked glycosyl structures may be added. The signal for the addition of these N-linked sugars is the same for yeast and mammalian glycoproteins (Asn-X-Ser/Thr). O-linked oligosaccharides may also be added. Proteins are then transported in vesicles to the Golgi where modifications to these glycosyl structures take place. These modifications differ from those made by higher eukaryotic cells and, as a result, glycosylation is increasingly regarded as a major drawback to the secretion of therapeutic glycoproteins from yeast. From the Golgi, proteins are packaged into secretory vesicles and are delivered to the cell surface (Figure 6).

Once in the ER, it is probable that a default pathway directs a protein to the plasma membrane unless it contains specific signals to cause retention in the ER or Golgi, or to target it to the vacuole. Therefore it might be thought that if a foreign protein could be targetted to the lumen of the ER, it should be successfully secreted. However, there are a number of stages in the secretory process at which problems may occur. The yeast proteins which assist in folding and disulphide bond formation differ from their counterparts in higher eukaryotes and this may affect folding of foreign proteins. Malfolding can result in retention in the ER and degradation. There are also reports of proteins being retained in the Golgi, again possibly due to malfolding. Retention in the cell wall has also been a problem, especially with larger proteins, although factors other than molecular mass are known to be important. In addition to problems of transport, other undesirable events such as aberrant processing or hyperglycosylation may take place during the secretory process. It should be noted, however, that proteins which are poorly secreted from *S.cerevisiae* may be efficiently secreted from other yeasts, for

ample prochymosin secretion is much more icient from *K.lactis* and *Yarrowia lipolytica* an from *S.cerevisiae* (see 'Expression in non-*ccharomyces* yeasts').

The secretion of heterologous proteins from yeast s been most successful with peptides, many of iich are commercially important, e.g. epidermal owth factor (EGF) and insulin. In high-density ltures hundreds of milligrams of these proteins ay be secreted per litre. The secretion of large pro-ns has proved less predictable, nevertheless there ve been some notable successes.[186,284,388] The ccessful secretion of proteins which are not natur-ly secreted, such as HIV-1 protease has also been ported,[288] but the presence of fortuitous ycosylation sites can cause problems.[307]

ctors and signal sequences

omoters and selectable markers Most commonly-ed secretion vectors are based on high-copy, 2μ asmids. Integrated vectors have been reported to ve higher yields of secreted product than episomal ctors; four integrated copies of a prochymosin pression unit resulted in similar overall expression vels but higher secretion yields than were achieved ith a multi-copy vector.[357] The reason for this fference is unclear. However, yields of EGF, which contrast to prochymosin is efficiently secreted, ere not higher from integrated gene copies.[74] Sakai al.[322] compared secretion of human nerve growth ctor from a 20-copy *Ty* δ-integrant with that from 2μ vector. Levels were three- to four-fold higher –4 mg/l) from the δ-integrant, but the use of a nstitutive promoter (*PGK*) may have led to copy umber reduction with the 2μ vector.

A number of the promoters described above (see 'ranscriptional promoters and terminators') have en used in secretion vectors, but frequently a pro-oter and signal sequence from the same gene are osen e.g. *MFα1*, *PHO5* or *SUC2*. Ernst[110] ported that up to a two-fold increase in somato-edin-C secretion could be obtained by using the eak *CYC1* promoter rather than the moderate tin promoter. Product toxicity may be more acute ith powerful promoters and this may work to duce plasmid copy number; the use of weak or oderate constitutive promoters, or regulated pro-oters which are repressed during early growth hases, may minimize this effect.

The choice of selection marker on a secretion vec-or may be particularly important since culture con-itions may dramatically affect the final yield in the edium. Selection of plasmid-containing cells in a defined medium may result in lower cell density and, in some cases, lower levels of secreted product per cell. Wheat α-amylase secreted from yeast has been shown to reach much higher levels in rich medium than in selective, defined medium.[314] At laboratory scale, it may be preferable therefore to use a dominant marker such as that for G418 resistance.

The nature of signal sequences A classical signal sequence comprises a charged N-terminus, a central hydrophobic core and a consensus sequence for cleavage in the ER by signal peptidase. Some secreted proteins, such as the yeast mating pheromone, α-factor, have additional pro sequences which may aid secretion.

As described below, heterologous proteins may be secreted from yeast using either a foreign signal, often derived from the protein being secreted, or a yeast signal. Since signal sequences are recognized with low specificity in yeast,[205] it could be assumed that foreign signals would work as efficiently as those from yeast, but this is often not the case.

A number of studies aimed at identifying the features of yeast signal peptides have been performed. Ngsee *et al.*[267] analysed mutated signal sequences from the yeast invertase gene, *SUC2*. They concluded that the essential feature of a signal peptide is a hydrophobic core of 6–15 amino acids, which may be interrupted by non-hydrophobic residues. Additionally, many signal peptides were found to contain one or more basic amino acids preceding the hydrophobic core. Small neutral and α-helix-disrupting amino acids were often present in the vicinity of the cleavage site.

Secretion of α-factor was shown to be drastically reduced if the hydrophobic core of the signal was interrupted by a hydrophilic residue, or a proline which disrupts-helical secondary structure.[4] Ngsee and Smith[268] noted that yeast invertase signal sequence is predicted to have an α-helical conformation, whereas that of bovine prolactin has a tendency to form an extended coil. Substitutions in the prolactin signal which increased the probability of it having an α-helical conformation improved its functioning in yeast. Thus there may be more stringent requirements for an α-helical secondary structure in yeast signal sequences compared to those of higher eukaryotes.

Surprisingly, even if the signal peptide is deleted, some proteins, e.g. carboxypeptidase Y[36] and acid phosphatase,[349] may still inefficiently enter the secretory pathway, indicating that the mature protein sequence may also contain features which can be recognized by elements of the secretory pathway.

Use of heterologous signal sequences Early attempts to secrete foreign proteins from *S.cerevisiae* utilized the protein's own signal sequence, e.g. *E.coli* β-lactamase,[303] human α- and γ-interferon (IFN),[173] mouse immunoglobulin heavy and light chains[406] and influenza virus haemagglutinin.[191] However the expression levels were often very low, with only a proportion of the protein being secreted. Processing of the polypeptide was not always correct and, in the case of IFN, degradation of the preprotein took place.[173] Nevertheless, some foreign proteins have been successfully secreted from yeast using their own signal, e.g. *Aspergillus awamori* glucoamylase,[186] barley α-amylases 1 and 2[358] and human serum albumin (HSA).[355] De Baetselier *et al.*[89] have reported the production of up to 3 g/L of active, secreted *Aspergillus niger* glucose oxidase.

The secretion from yeast of *Bacillus amyloliquefaciens* α-amylase[316] using its own signal demonstrated that a prokaryotic signal sequence may also efficiently direct secretion. The signal peptide was correctly cleaved, but the α-amylase was core glycosylated in contrast to the native product. However, the glycosylated enzyme retained its activity.

Foreign signals may also be used to drive secretion of other heterologous proteins—the human gastrin signal sequence has been shown to drive secretion of human α-amylase in *S.cerevisiae*.[328] In general, the heterologous signal sequences which function best in *S.cerevisiae* tend to be those from plant or fungal proteins (e.g. barley α-amylase,[358] *Trichoderma reesei* endoglucanase,[388] *Mucor pusillus* aspartic proteinase[410]).

The leader sequence from the killer toxin *ORF2* gene of *K.lactis*, a yeast closely related to *S.cerevisiae*, has been employed to direct the secretion of human interleukin-1β[15] and diphtheria toxin-hormone fusion proteins.[285] HSA has also been secreted from *S.cerevisiae* using this leader sequence, however it was shown to be less efficient than the native HSA leader or an *S.cerevisiae* signal sequence.[355]

Although there have been some notable successes, the use of foreign leaders often results in intracellular accumulation (e.g. α-IFN,[173] α-1-antitrypsin[53]), and it must be concluded that the yeast secretory pathway has slightly different requirements from higher eukaryotic secretion systems. Therefore, for most cases of heterologous protein secretion from yeast, it is preferable to use a yeast signal sequence and it may be simpler to do this as a matter of course with a new gene.

Use of yeast signal sequences Owing to the difficulty of predicting whether a particular foreign signal sequence will function in yeast, much work has been carried out using homologous *S.cerevisiae* signal sequences. The three most widely studied are those from acid phosphatase, invertase and α-factor.

Acid phosphatase (*PHO5*) has a classical signal sequence[7] yet there are few examples of its use for heterologous protein secretion. When used to secrete tissue-type plasminogen activator (tPA), less than 5% of the total tPA activity was found in the medium,[169] however the secretion of this protein has been problematic.[231] Human salivary α-amylase has been secreted using the *PHO5* signal[328] which in this instance gave similar results to the heterologous α-amylase and human gastrin signals and to the yeast α-factor leader.

The yeast invertase (*SUC2*) signal[286] has been used more widely for foreign protein secretion. Human α2-IFN has been secreted using this signal, which was correctly cleaved from all secreted molecules[59] unlike the native IFN signal peptide.[173] The invertase signal has also been used to secrete human α-1-antitrypsin (α-AT), however approximately 80% of the protein remained inside the cell.[262] The passage of the α-AT from the ER appeared to be the rate-limiting step in this case. Production of mouse–human chimaeric antibody has been achieved using the invertase signal to secrete immunoglobulin heavy and light chains.[180] Melnick *et al.*[255] reported the efficient secretion of human single-chain urinary plasminogen activator (scuPA) using the invertase signal.

Attachment of a heterologous protein to a yeast signal sequence will usually result in a change in the amino acid immediately C-terminal to the signal peptidase cleavage site. However, there appears to be flexibility in recognition of cleavage junctions. Fusions of the invertase signal with proteins which alter the amino acids at the junction, such as HSA or two forms of insulin, are still cleaved.[171]

The most extensively used signal sequence for heterologous protein secretion from *S.cerevisiae* is the prepro region from α-factor (*MFα1*), frequently used with the *MFα1* promoter. *MFα1* encodes a 165 amino acid protein, prepro-α-factor, which comprises a signal sequence of 19 amino acids (the pre region) and a pro region, followed by four tandem repeats of the mature 13 amino acid α-factor sequence (Figure 7). Each repeat is preceded by a short 'spacer peptide' with the structure Lys-Arg-(Glu/Asp-Ala)$_{2-3}$. Processing of prepro-α-factor

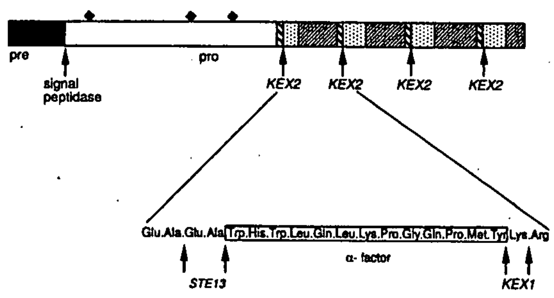

Figure 7. The structure and processing of prepro-α-factor. The product of the *MFα1* gene is shown schematically. The three N-linked glycosylation sites in the pro region are marked (◆). The peptide product from the cleavage of prepro-α-factor by KEX2 is also indicated and sites for further processing by STE13 and KEX1 are shown. See text for a description of the activities of the processing enzymes.

involves four proteolytic enzymes: (i) the pre region is cleaved by signal peptidase, (ii) the KEX2 protease cleaves on the carboxyl terminal side of the Lys-Arg sequence in the pro region and at the junction of each repeat, (iii) STE13, a dipeptidyl aminopeptidase, removes the spacer residues at the amino terminus of each repeat and (iv) the KEX1 carboxypeptidase removes the Lys and Arg residues at the carboxyl terminus of the first three repeats (see Figure 7; reviewed in reference 41).

Fusions of the *MFα1* prepro to genes encoding mature human α1-IFN,[350] a consensus α-IFN,[34] β-endorphin[34] or human EGF (hEGF)[42] resulted in efficient secretion of the heterologous protein. Processing of the prepro region took place, but the Glu-Ala spacer at the N-terminus of the secreted protein was not always removed. 5% of the hEGF and 50% of the α1-IFN was estimated to be in an intracellular form. Many foreign proteins have now been secreted from yeast using the α-factor leader, and this system has been demonstrated to be generally applicable. Changes can be made to the *MFα1* prepro to facilitate cloning, such as the introduction of a *Xho* I site towards the end of the pro region.[74] Despite a resultant amino acid change (Asp to Glu), this was shown to be fully functional.

The requirement for the pro region of the α-factor signal sequence seems to vary. Glycosylation of this region appears to be important for efficient transport of α-factor.[55] Ernst[111] reported that the pro region was not important for the secretion and processing of aminoglycoside phosphotransferase or human granulocyte-macrophage colony stimulating factor (GM-CSF). Furthermore, prepro fusions to interleukin-1β were not cleaved whereas pre fusions were correctly processed.[111] However, secretion of human insulin-like growth factor I (IGF-I) from yeast is dependent on the entire α-factor leader; the pre region is not sufficient. It may be that the pro region aids movement of the IGF-I into the ER or assists folding of the protein in the ER (A. Hinnen, personal communication). Additionally, both the pre and pro regions were required to bring about translocation of a reporter protein, α-globin.[312] Reppe *et al.*[296] compared secretion of human parathyroid hormone (hPTH) directed either by the α-factor prepro region or by the pre region alone. When the pro region was not present, there was a considerable reduction in hPTH mRNA levels, with a concomitant reduction in levels of the protein product both in the growth medium and inside the cells. This suggests that the pro region may additionally play a role in stabilizing the mRNA or may affect transcription of the gene.

Glycosylation

Many potential therapeutic proteins are glycosylated, including monoclonal antibodies, blood clotting factors, and many IFNs, hormones, growth factors and viral antigens. The carbohydrate side chains appear to be involved in diverse processes including cell–cell recognition, hormone–receptor binding, protein targetting, host-microorganism interactions, solubility and stability.[295] Glycosylation is both organism and cell-type specific and

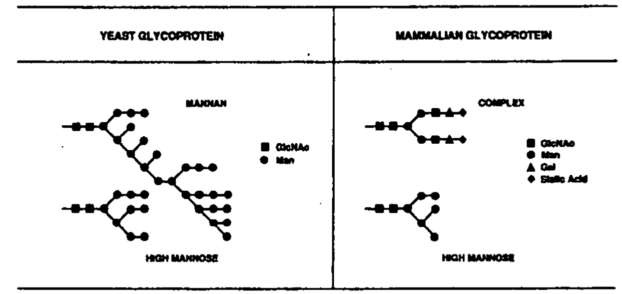

Figure 8. Comparison of yeast and mammalian glycosylation. Schematic diagram to compare the structures of oligosaccharide side chains of glycoproteins produced in yeast and mammalian cells.

therefore expression of a protein in a heterologous system will almost certainly result in a product with different modifications from the native material. This may affect the function or immunogenicity of the protein. It is interesting to note that differences in glycosylation of tPA produced in either Chinese hamster ovary or murine cell lines led to differences in the kinetics of its fibrin-dependent activation of plasminogen.[280]

Oligosaccharides may be either N-linked to asparagine or O-linked to serine or threonine residues. O-linked oligosaccharides synthesized by yeast are very different from those of higher eukaryotes, being composed only of mannose residues. Many higher eukaryotic proteins have sialylated O-linked chains of the mucin-type. N-linked glycosylation in yeast and higher eukaryotes is more conserved, and entails the addition in the ER of a core oligosaccharide unit comprising two N-acetylglucosamine (GlcNAc), nine mannose (Man) and three glucose residues. The glucose residues are subsequently trimmed from the side chain and one mannose is also removed. These steps are common to yeast, plants and higher eukaryotes.

Processing of the core oligosaccharide unit takes place in the Golgi and at this stage there is divergence between yeast and other eukaryotes (Figure 8). In animal cells further mannose residues are removed and additional sugars may be added. The resultant oligosaccharide side chains are of three types: (i) high-mannose ($GlcNAc_2Man_{2-6}$), (ii) complex, which comprises a core of $GlcNAc_2Man_3$ plus additional residues including GlcNAc, galactose (Gal), fucose and sialic acid, and (iii) hybrid, containing features of both high-mannose and complex-type oligosaccharides. (N-linked glycosylation is reviewed in reference 221). In contrast, *S.cerevisiae* does not trim back the mannose residues as it lacks the Golgi mannosidases present in higher eukaryotes. Instead, elongation of the chain may take place through a stepwise addition of further mannose residues. These additional mannose units comprise the outer chain which may be up to 75 residues long, with many branch chains. (For a review of protein glycosylation in yeast see reference 225).

Many heterologous glycoproteins have been secreted from yeast, including *Aspergillus* glucoamylase,[186] somatostatin,[148] human α-1-antitrypsin,[262] porcine urokinase,[417] human erythropoetin[106] and *Trichoderma reesei* endoglucanase I.[388] The addition of both N- and O-linked oligosaccharides has been reported (e.g. *Aspergillus* glucoamylase[186]). Analysis has revealed that not all *S. cerevisiae* N-linked oligosaccharides contain the outer chain of mannose residues. Addition of the outer chain to heterologous proteins is regarded as 'hyperglycosylation' because it results in more extensive glycosylation than is found in higher eukaryotic glycoproteins. Additionally, it should be noted that glycosylation can be very heterogeneous, giving rise to a mixed product with a varying degree of oligosaccharide attached.

Some foreign proteins are fortuitously glycosylated when secreted from yeast. This problem is more likely to occur with proteins from bacteria (for example see references 307 and 316), in which there is no glycosylation, or with proteins which are not normally secreted. Interleukin (IL)-1α and 1β are naturally-secreted proteins, but do not pass through the normal secretory pathway in mammalian cells,

.re therefore not glycosylated. However, when ted from yeast using a signal sequence, both ins are glycosylated. Although this has no sig- .nt effect on the biological activity of IL-1α,[233] :tivity of IL-1β is reduced five-fold.[234]
though many glycoproteins produced in yeast ıctive, yeast glycosylation, especially hyper- ısylation, may give rise to problems, depend- ın the intended use for the protein. In some nces, extensive glycosylation may inhibit ivity with antibodies, as was the case for EBV 0 secreted from *S.cerevisiae*.[335] This is ɔusly an undesirable effect for potential vaccine :ens. Furthermore, α1,3-linked mannose units, h occur in large numbers in the outer chain, ar to be immunogenic[16] and thus yeast-derived ›proteins may be unsuitable as therapeutics.
oblems with yeast glycosylation of foreign pro- may be circumvented by mutating the glycosy- n site(s), as was done in the case of scuPA[255] to a fully-active, non-immunogenic product. rnatively, the use of glycosylation mutants vs the production of more homogeneous pro- with limited glycosylation. Mutants in mannan ynthesis (*mnn*) may be useful for the production :terologous proteins; *mnn9* mutants do not add :xtensive outer chain of mannose units,[225] how- immunogenic terminal α1,3 mannose linkages till present. Use of the *mnn1 mnn9* strain, which tionally lacks these residues, may enable the luction of non-immunogenic, non-hyperglyco- :ed proteins. However some *mnn* mutants, e.g. 9, exhibit slower growth and greater osmotic itivity than wild-type cells. Sledziewski *et al.*[353] ted a strain in which *MNN9* expression was ɔerature-regulated, using the α2 repressor sys- in a *MAT*a *sir3*[ts] strain (see 'Transcriptional noters and terminators'). Cultures were grown igh density at the permissive temperature for *N9* expression (25°C), then switched to the non- nissive temperature (35°C). Glycoproteins pro- :d at the higher temperature were shown to have shorter, homogeneous mannose side chains :acteristic of *mnn9* mutants.
ome 'super-secreting' mutants are also hyper- osylation-deficient and may be suitable host ins for glycoprotein production. *pmr1* mutants viously called *ssc1*; see below) possess a defec- Ca^{2+} ATPase ion pump and their growth is ium-dependent.[315] The mutation is thought to se secreted proteins to by-pass the Golgi. Pro- s secreted from this strain are core-glycosylated y.

Protein folding and transport

Folding of secreted proteins occurs in the ER and involves accessory proteins such as BiP (heavy chain binding protein, the product of the *KAR2* or *GRP78* gene[272,309]), and protein disulphide isomerase.[126] Nascent proteins bind to BiP co-translocationally and are released upon folding, assembly and glycosylation; malfolded proteins bind permanently and are retained in the ER. The assembly of an oligomeric bacterial enterotoxoid in *S.cerevisiae* has recently been shown to be dependent on BiP, which acts as a molecular chaperone.[333] During the secretion of foreign proteins, problems might arise either from saturation of these accessory proteins or from their inability to aid the folding of heterologous proteins.

Glycosylation of a protein can aid both generation of the correct conformation and passage of the molecule through the secretory pathway. Inhibition of glycosylation with tunicamycin results in the intracellular accumulation of inactive invertase.[136] At lower temperatures, unglycosylated protein may be secreted: at 25°C, 50% of unglycosylated invertase is secreted.[116] Similarly, active, unglycosylated acid phosphatase can be secreted from tunicamycin-treated cells at 20°C or 25°C, but not at 30°C.[259] Unglycosylated glycoproteins are transported only if they achieve the correct conformation and the lower temperature allows this to happen. Progressive elimination, by mutation, of each of the 12 glycosylation sites of acid phosphatase resulted in increasing irreversible retention of the malfolded protein in the ER as more sites were removed.[299] At lower temperatures under-glycosylated or unglycosylated protein could be secreted.

Sato *et al.*[328] studied the expression of a series of human salivary α-amylase mutants which either lacked regions encoding cysteine residues or contained mutations at cysteine codons. The prevention of the possible formation of a disulphide bond abolished secretion. Elimination of either of the two glycosylation sites did not affect secretion and indeed α-amylase is secreted from tunicamycin-treated cells in a fully active form. Thus, at least for α-amylase, the unique conformation of the protein appears to be much more important than glycosylation for secretion in yeast. This phenomenon indicates that attempts to secrete protein fragments or fusions could lead to intracellular accumulation if normal folding and disulphide bond formation cannot take place.

In addition to requiring successful targetting and folding in the ER, a foreign protein also has to pass

through the secretory organelles in order to be released into the culture medium. Transport from the ER to the Golgi has often been shown to be rate-limiting. Hepatitis B virus large surface protein is retained in the ER, provoking the enlargement of this organelle.[31] This retention may be due to malfolding or to a specific retention signal. α-1-antitrypsin[262] and erythropoetin[106] are also retained in the ER. Soybean proglycinin, although expressed to high levels and correctly processed, was mostly insoluble and accumulated in Golgi-like structure.[386] Insolubility was due to interaction of the acidic region of the polypeptide with cellular components.[386] A Golgi or post-Golgi bottleneck was also postulated to represent a major obstacle in the secretion of IGF-I.[367] Retained material may have been malfolded and this is likely to be a common reason for intracellular accumulation of proteins within the secretory pathway.

A blockage or bottleneck in the secretory pathway caused by foreign protein secretion may also interfere with the secretion of host proteins. This was observed for acid phosphatase during the secretion of tPA[169] and may result in toxicity.

Correct folding, assembly and transport are especially important in the production of multimeric proteins. The first multimeric protein to be secreted from yeast was a mouse-human chimaeric antibody. Co-expression of immunoglobulin heavy and light chains resulted in the secretion of properly folded and assembled antibody.[180] Both whole antibody and Fab fragments were functional. The pentameric *Torpedo californica* nicotinic acetylcholine receptor with a stoichiometry $\alpha_2\beta\gamma\delta$ has also been produced in yeast by co-expression of the four subunits.[199,412] These integral membrane proteins entered the secretory pathway and were processed and glycosylated. However, no functional receptor was detected, possibly due to improper folding or assembly.

Membrane proteins often cause problems when secreted due to non-specific insertion into intracellular membranes (see 'Physiology of foreign gene expression'). EBV membrane glycoprotein gp350 was highly toxic, but could be secreted in a membrane anchor-minus form.[335] Nevertheless, some membrane proteins have been successfully produced in yeast. The human β_2-adrenergic receptor was co-expressed with a mammalian G protein.[214] Coupling of these components to each other and to downstream effectors of the yeast mating signal transduction pathway was demonstrated, indicating that correct folding and targetting took place. This *in vivo* reconstruction system provides a useful new approach for the study of signal transduction pathways.

The presence of the cell wall complicates the secretion process in yeast. Permeability may be a limiting factor and it is notable that most success has been with very small proteins. Some proteins have been reported to be localized mainly in the cell wall when secreted from *S.cerevisiae*, e.g. α-IFN[420] (166 amino acids, 20 kDa). Although it has been reported that only molecules with a molecular mass below 760 are able to diffuse freely through the cell wall, a number of very large proteins such as EBV membrane glycoprotein[335] (842 amino acids, approximately 400 kDa) and cellobiohydrolase[284] (up to 200 kDa) have been shown to be capable of passing through the cell wall and therefore this property is not related simply to the size of the molecule. It may be that there are a few large holes in the cell wall with the average pore size being small. It is difficult to draw conclusions from observations of permeability since many other factors, including strain, growth phase and composition of the medium, may have an effect on cell wall porosity (reviewed in reference 91). Additionally, glycosylation and the charge on a protein are thought to affect its passage through the cell wall. *mnn9* mutants have been reported to have increased porosity and release invertase octamers, which are normally retained.[373] *kre1* mutants, which have altered (1,6)-β-D-glucan in the cell wall, over-secrete secreted yeast proteins, possibly due to the cell wall being more leaky.[51]

Proteolytic processing

There are two ways in which proteolytic processing is relevant to heterologous protein secretion in yeast. Firstly, correct processing of the signal peptide or prepro region must take place so that the mature product is secreted. Secondly, fortuitous, undesirable processing events may occur as a result of cleavage by processing proteases.

Yeast signal peptidase (SPase) is a polypeptide complex which includes the *SEC11* gene product and a glycoprotein.[407a] Although eukaryotic SPases and the *E.coli* SPase I are disparate, it is interesting to note that homologous overproduction of the *E.coli* protein resulted in increased efficiencies of export and maturation of two poorly-processed hybrid secretory proteins.[392] This indicates that, at least in *E.coli*, the availability of the SPase can be a limiting factor. Indeed, *S.cerevisiae* strains carrying multiple copies of the wild-type *PHO5* gene

accumulate unprocessed precursor, suggesting that there is saturation of some component of the secretory pathway, possibly SPase.[155]

Deletion of the SPase cleavage site in yeast acid phosphatase leads to unprocessed, core glycosylated protein which accumulates inside the cell.[155] However, even where processing of the signal does take place, cleavage may be aberrant, giving rise to heterogeneous product. 64% of human IFN secreted from yeast using its own signal was properly processed, but 36% contained an additional three amino acids of the pre sequence.[173] Furthermore, 90% of the total IFN produced was not secreted and this intracellular material also included a third form which retained eight amino acids of pre sequence. It is unlikely that molecules which retain part or all of the pre sequence will be secreted since the hydrophobic core may be retained in the membrane.

The processing of the prepro sequence from α-factor has been described above and is a more complex process involving the *KEX2* and *STE13* gene products in addition to signal peptidase (reviewed in reference 49). The KEX2 protease cleaves on the carboxyl side of the dibasic residues, Lys-Arg and Arg-Arg. In a fusion of the α-factor prepro and a heterologous protein, these residues are at the junction, and cleavage by KEX2 liberates the heterologous protein from the leader region. The Glu/Asp-Ala spacer residues, which provide a hydrophilic environment at the KEX2 cleavage site can be dispensed with in certain cases, circumventing the problem of incomplete STE13 processing, e.g. for hEGF[42] and α1-IFN.[350] However, removal of the spacer peptide does sometimes lead to a failure in KEX2 processing, as observed for interleukin-6 (IL-6)[152] where the presence of a proline residue on the carboxyl side of the cleavage site inhibited cleavage. However, accurate recognition and cleavage occurred when the construct was modified to include alanine N-terminal to the proline. Expression of the modified gene fusion had then to be carried out in a *ste13* mutant, to avoid trimming at the N-terminus of IL-6 by the STE13 protease.

Another solution to the problem of inefficient processing is to over-express the processing enzyme genes. This approach was successfully employed in the expression of transforming growth factor α (TGFα).[19] Inclusion of the *KEX2* gene on the same multi-copy plasmid as the TGFα gene eliminated the presence of unprocessed forms of the α-factor leader-TGFα fusion protein and resulted in increased levels of secreted TGFα. Additionally, a novel *S.cerevisiae* aspartyl protease (*YAP3*) has been identified which allows KEX2-independent processing of the α-factor precursor.[102] This could be over-expressed when KEX2 processing was inefficient and limiting. Over-expression of *STE13* could also improve inefficient processing; wild-type cells carrying multiple copies of the *MFα1* gene produce mainly incompletely processed α-factor, indicating that the dipeptidyl aminopeptidase is rate-limiting.[204]

In addition to inefficient proteolytic processing, problems may also be caused by aberrant processing at internal sites in the protein. In the extreme case of β-endorphin, no complete mature protein was secreted into the medium;[34] two trypsin-like cleavage sites were observed after internal lysine residues. Use of the vacuolar protease mutant *pep4-3* did not reduce the degradation, suggesting that proteolysis was taking place during passage through the normal secretory pathway.[34] Internal processing was also a problem in the expression of hPTH in which cleavage, probably by the *KEX2* gene product, was observed after two basic residues.[131] A mutant form of hPTH which lacked one of the basic residues was no longer subject to internal proteolytic processing.[297] The mutant form retained full biological activity and was produced in significantly higher yield. Differences in proteolysis between strains and/or growth conditions may exist since two reports of secretion of GM-CSF identified different aberrant processing events. Miyajima *et al.*[257] reported cleavage after the arginine residue at position 4 of the mature protein. Price *et al.*[290] however observed both the full-length mature species and the product of cleavage after the proline at position 2 of the mature protein. Differences were also apparent in the efficiency of α-factor leader processing. This indicates that it may be possible to eliminate or to minimize internal cleavage of heterologous proteins by optimizing growth conditions and selecting the best strain.

An analysis of secreted hirudin (hir) revealed full-length hir65, but also two C-terminally degraded products, hir64 and hir63.[372] Use of the protease mutants *prc1* and *kex1* showed that this degradation was due both to yscY and yscα activities. Similarly, secreted EGF was found to be C-terminally trimmed.[74,138]

Mutants in the gene for the extracellular protease SKI5 were shown to give higher yields of secreted yeast proteins due to decreased degradation in the medium.[51]

An interesting development in protein production has been the exploitation of yeast processing

enzymes to cleave heterologous precursors. Proinsulin is converted to insulin as the result of cleavage at two dibasic sequences separated by a spacer peptide. These processing reactions can be carried out by the KEX2 protease, and various forms of proinsulin/insulin have been secreted from yeast.[376] Human proalbumin has also been shown to be processed after the Arg-Arg sequence by KEX2 to yield mature albumin.[21] *Aspergillus* glucoamylase secreted from yeast using its own signal sequence was shown to be cleaved both by SPase and by KEX2, which removed an additional six amino acids from the N-terminus.[186] This yielded a product with the same N-terminus as that of the *Aspergillus* enzyme and showed yeast to be capable of this additional processing step.

Strategies to improve secretion

Several *S.cerevisiae* strains with a 'super-secreting' phenotype have been isolated by screening for mutants with increased secretion of a particular product. Such methods have yielded strains which show a general increase in heterologous protein secretion. On finding that less than 1% of the prochymosin made in yeast was secreted, Smith *et al.*[357] employed a mutagenesis approach coupled with a rapid screening assay to isolate super-secreting colonies. The secreted material, which was activated by the low pH of the medium, was assayed by overlaying the surface of the plate with a mixture of milk and molten agarose. The chymosin clots the milk and the speed of appearance of the opaque clotted regions and their size and intensity indicate the level of prochymosin secretion. Two super-secreting strains in particular were identified and designated *ssc1* and *ssc2*.[357] The effects appeared to be additive in the double *ssc1 ssc2* mutant. The *SSC1* gene was later found to be identical to *PMR1*, which encodes a Ca^{2+} ATPase[315] (see above). The *pmr1* mutation significantly increased the secreted levels of prochymosin, bovine growth hormone and scuPA by five- to 50-fold.[357,384] However secretion of α-1-antitrypsin, which was efficiently exported in the wild-type strain, was not further improved, indicating that the *pmr1* mutation may be most effective at improving the secretion efficiency of proteins that are secreted poorly by wild-type cells.

In addition to using colony assay screens to find the most efficient secretors, Moir and Davidow[261] described a screening procedure which involved *in vitro* mutagenesis of scuPA genes on plasmids. This enabled identification of mutant forms of scuPA with either decreased or increased activity compared to the parental form. The assay uses fibrin-agar and colonies are scored by measuring zones of clearing.

Other workers have employed a similar approach to identify super-secreting strains. A plasminogen-casein assay for secreted tPA was used to isolate secretor strains;[141] previous attempts to secrete tPA from yeast had not been successful.[169,231] A general screen for secreted proteins based on a visual antibody precipitation assay has been described.[354] Repeated rounds of mutation and selection enhanced the secretion of HSA six-fold and the resultant strains were also able to produce higher levels of internally-expressed α-1-antitrypsin and human plasminogen activator inhibitor 2. This screen is suitable for any protein for which antibodies are abundantly available. Multiple rounds of mutagenesis and selection were also used to isolate a strain which secreted 70-fold more endoglucanase I than the original wild-type parent strain.[6] Again, the mutant strain was found to secrete elevated levels of other proteins.

By expressing a gene fusion of HSA and hygromycin B phosphotransferase, Chisholm *et al.*[68] selected for increased expression on the basis of the level of resistance to hygromycin B. This method was initially used to isolate strains with increased intracellular expression of the HSA fusion protein. However, when cured of the intracellular expression vector and retransformed with a HSA secretion vector, these strains also showed significant increases in secretion. Genetic analyses suggested that multiple mutations were responsible for the observed effects.

Selection may be used to identify mutants which are resistant to the toxic effects of a foreign protein. The slow growth rate of IGF-I-expressing cells was exploited by Shuster *et al.*[347] who isolated fast-growing IGF-I-resistant mutants which gradually accumulated in a population of IGF-I-expressing cells under selection. Mutations at a single locus, designated *HPX1* (for *H*eterologous *P*rotein e*X*pression) were found to confer both resistance to the toxic effects of IGF-I and its increased production.

In summary, the screening approach has frequently proved successful in the isolation of super-secreting strains, even in cases where the initial yield was high. Therefore, for industrial applications when a high yield is required, this approach deserves consideration.

Table 6. Comparison of the expression of two genes in *E.coli*, Baculovirus, *S.cerevisiae* and *P.pastoris*.

Expression system	Expression level (%) Fragment C	Pertactin
E.coli	24[241a]	30[242a]
Baculovirus	10‡,[60a]	>40*
S.cerevisiae GAL7	2–3[307]	0·1[306]
P.pastoris	28§,[73]	10¶,[306]

EXPRESSION IN NON-*SACCHAROMYCES* YEASTS

Introduction

In some ways *S.cerevisiae* could be regarded as a non-optimal host for the large-scale production of foreign proteins due to drawbacks such as the lack of very strong, tightly-regulated promoters, the need for fed-batch fermentation to attain high-cell densities, and hyperglycosylation. Although these have been addressed by exploiting its sophisticated molecular genetics, another important approach has been to develop expression systems in other yeasts. Most of these alternative systems are based on commercially-important yeasts that have been selected for their favourable growth characteristics at industrial scale, or on yeasts which have other favourable intrinsic properties (e.g. high-level secretion).

The most extensively developed system is based on *Pichia pastoris*. An efficient and tightly-regulated promoter coupled with very straightforward techniques for high-biomass cultivation make this a powerful expression system. It is currently the simplest of eukaryotic systems to scale up, and there are now several comparative studies suggesting it can be used to avoid limitations on transcription which are sometimes encountered with *S.cerevisiae* (see Table 6). *Hansenula polymorpha* has similar properties and there are some promising examples of its use. A potential problem however, especially with toxic products, may be that under the conditions normally used for high-density growth, expression is significantly derepressed. *K.lactis* and *Y.lipolytica* are both industrial yeasts which have been examined largely because of their capacity for high-level secretion. *K.lactis* is similar to *S.cerevisiae* and has well-developed molecular genetics. Unlike the other systems discussed here it has the advantage of highly stable episomal vectors. Finally the distantly-related fission yeast, *S.pombe*, has very advanced genetics but its use in foreign gene expression has mainly been in isolating and studying homologous mammalian genes, rather than protein production. The following sections will briefly review these non-*Saccharomyces* heterologous expression systems. A summary of the various proteins that have been expressed in each system is given in Table 7.

Pichia pastoris

The methylotroph *P.pastoris* has now been used to express high levels of many different intracellular and secreted proteins. Strains were originally developed for the large-scale, high-yield production of single-cell protein using defined medium containing methanol.[401] This fermentation technology subsequently provided the basis for an efficient expression system which uses the promoter from the tightly-regulated *AOX1* gene.[81] *AOX1* encodes alcohol oxidase, which catalyses the first step in the assimilation of methanol, and can be induced to give levels of up to 30% of t.c.p. by the addition of methanol.[76]

Since *P.pastoris* has no native plasmids (other than linear DNAs, K. Sreekrishna, personal communication) expression vectors designed for chromosomal integration have been developed. These vectors have used the *HIS4* gene for selection, but a limited number of alternative selection markers are now available, e.g. *ARG4* from *S.cerevisiae*[80] or *P.pastoris* (J. Cregg, personal communication), the *Tn903* G418-resistance gene (K. Sreekrishna personal communication), and the *S.cerevisiae SUC2* gene[361] which can be used as a dominant marker since *P.pastoris* cannot use sucrose as the sole carbon source. Multi-copy episomal vectors containing the *P.pastoris* ARS sequences, PARS1 and PARS2, have also been constructed.[79] However, for maximum stability, particularly in large-scale inductions, the expression cassette has been transplaced into *AOX1*, or integrated by single cross-over into *AOX1* or *HIS4* (see Figure 9). It is worth noting that, using *HIS4* selection, *HIS4* integrants are the least stable type of transformant since recombination can result in excision of the expression cassette leaving behind a wild-type marker. Although transplacement into

AOX1 results in gene disruption, transformants are still capable of slow growth on methanol due to the presence of a second alcohol oxidase gene, *AOX2*, which is less well expressed.[80]

The unusually high level of alcohol oxidase together with evidence for transcriptional regulation[107] suggested a very powerful and efficiently regulated promoter suitable for foreign gene expression. This was first tested by isolating the *AOX1* promoter, and also that from the co-regulated dihydroxyacetone synthase gene (*DHAS*), and fusing them to the *lacZ* gene.[380] In single-copy the *AOX1-lacZ* hybrid gene was tightly repressed by glucose or glycerol and was efficiently induced by methanol; with multi-copy *PARS* vectors some expression in glycerol occurred. The *AOX1* promoter has subsequently been used to produce a variety of foreign proteins. Promoters from several other *P.pastoris* genes have been isolated, e.g. from the constitutive *GAP* and *PGK* genes, and from the *AOX2* gene,[80] but there are no published examples of their use.

A number of factors may potentially affect expression levels using *P.pastoris* integration vectors. In particular, disruption of *AOX1* by transplacement might be expected to have important physiological consequences which may influence foreign gene expression. During induction *aox1* transformants do not simultaneously produce high levels of alcohol oxidase and heterologous protein, and they also grow more slowly ('*m*ethanol-*u*tilization *s*low', Mut^s), and have a much lower O_2 demand than wild-type (Mut^+) strains. Indeed, in the first report of foreign gene expression in *P.pastoris*, a higher proportion of immunogenic HBsAg particles were produced in a Mut^s host compared to Mut^+, although expression levels were similar.[81] This was attributed to one or more events during assembly being rate-limiting in fast-growing cells, though there is evidence that particle maturation in *S.cerevisiae* occurs during protein extraction.[399] The parameters affecting foreign gene expression in *P.pastoris* were investigated in a study using tetanus toxin fragment C.[73] In a direct comparison, similar amounts were produced in Mut^S and Mut^+ hosts, even at levels approaching 28% t.c.p. Expression levels were also independent of the site (*HIS4 versus AOX1*) and type (single *versus* double cross-over) of integration. However, in another study, a Mut^S integrant expressed *Bordetella pertussis* pertactin at 2% t.c.p. in shake flasks and 10% t.c.p. in fermenters, while a Mut^+ strain gave 5–6% t.c.p. in shake-flasks or fermenters.[306] Thus, the significant physiological differences between Mut^S and Mut^+ strains during induction may in some instances influence the expression of foreign genes.

The abundance of alcohol oxidase led to the assumption that single-copy integrants would yield sufficient levels of foreign proteins using the *AOX1* promoter. However, with single-copy vectors it has not been possible to obtain yields of heterologous proteins that are as high as alcohol oxidase.[73,74,306] This is not due to the presence of DAS elements since, unlike the *S.cerevisiae PGK* gene[253], replacement of the *AOX1* coding region with foreign sequences does not affect mRNA levels[73] (R. Buckholz personal communication). Rather, higher levels of alcohol oxidase are probably due to its exceptional proteolytic stability which may be enhanced as a result of sequestration to peroxisomes. Multi-copy integrant strains are now used for increased yields of foreign proteins. These can be obtained using vectors containing multiple expression cassettes[375] or, for very high copy number, by screening for multiple integration events.[73,74,306] Surprisingly, very high copy number integrants can be isolated from transformations using DNA fragments designed for single-copy transplacement. Sreekrishna *et al.*[359] observed a high degree of variation (from 1–30% t.c.p) in the level of tumour necrosis factor (TNF) expressed in different Mut^S transformants and found this was due to differences in gene copy number.

The mechanism of this 'multi-copy transplacement' was initially unclear and it was not apparent whether this was a general phenomenon, nor whether high-level expression would invariably occur as a result. However, multi-copy transplacement has now been observed in several other instances.[73,74,306] The use of such strains has frequently resulted in remarkably high yields which compare very favourably with other expression systems (see Table 6). These studies also show that multi-copy transplacement strains are stable during high-density growth and induction. The clonal variation in vector copy number and protein yield among transplacement transformants expressing pertactin is illustrated in Figure 10.

Multi-copy transplacement occurs at a variable frequency, and is observed in about 1–10% of Mut^S transformants.[73,74,306] To understand the mechanism involved and the factors controlling this, Clare *et al.*[73] carried out a detailed DNA analysis of fragment C-vector transformants. An interesting finding was that 75–95% of transformants had not undergone a transplacement event (i.e. were Mut^+) but were single or multiple integrations at *AOX1* or

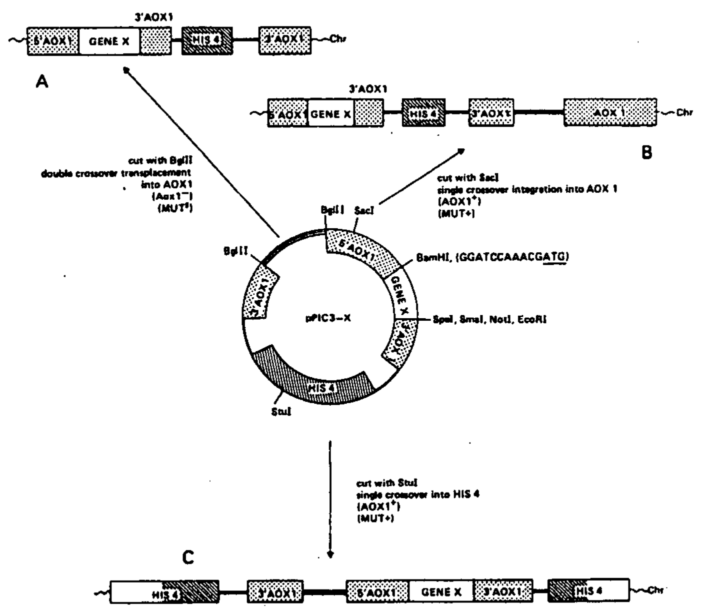

Figure 9. Plasmid map of the *P.pastoris* expression vector pPIC3 showing the three different modes of chromosomal integration. (A) Digestion with *BglII* yields a fragment with ends that are homologous to the 5' and 3' regions of *AOX1* that is targetted to transplace into *AOX1*. (B) Linearizing with *SacI* targets integration by single cross-over into *AOX1*. (C) Linearizing with *StuI* targets single cross-over integration into *HIS4*.

HIS4, or lacked vector sequences and were presumably *HIS4* gene convertants. The multi-copy transformants predominantly contained head-to-tail tandem arrays of the transplacing fragment located at *AOX1*. Both these and the other structures observed could be explained by intramolecular ligation of transplacement cassettes *in vivo*, prior to repeated single cross-over integration into *AOX1*, *HIS4* or into previously transplaced vector. Intermolecular ligation also occurred at low frequency since integrants containing the entire vector or head-to-head repeats were also found.

This mechanism of multi-copy formation (i.e. repeated single cross-overs of circularized transplacement cassettes) suggests that DNA fragments designed for targetted single cross-over integration rather than transplacement could be used to generate multi-copy transformants more readily, since higher transformation frequencies can be achieved. For the routine isolation of high-copy integrants, mass screening methods based on colony hybridization have been used[74,306] (Figure 10). More recently, vectors containing the G418-resistance marker have been used to identify high-copy integrants by resistance to increasing concentrations of the drug (K. Sreekrishna, C.A.S., unpublished results). Thus, the most efficient procedure for isolating high-copy integrants is probably to use these vectors in single-cross-over integrations and to select clones, from amongst primary His$^+$ transformants, that are resistant to high concentrations of G418 (e.g. 2 mg/ml). Multi-copy Mut^S clones can be obtained by using a strain carrying a disrupted copy of *AOX1* (e.g. KM71[80]).

With some foreign proteins there is a direct correlation between gene dosage and expression level, although the yield per expression unit is usually reduced at very high copy number. This can be clearly

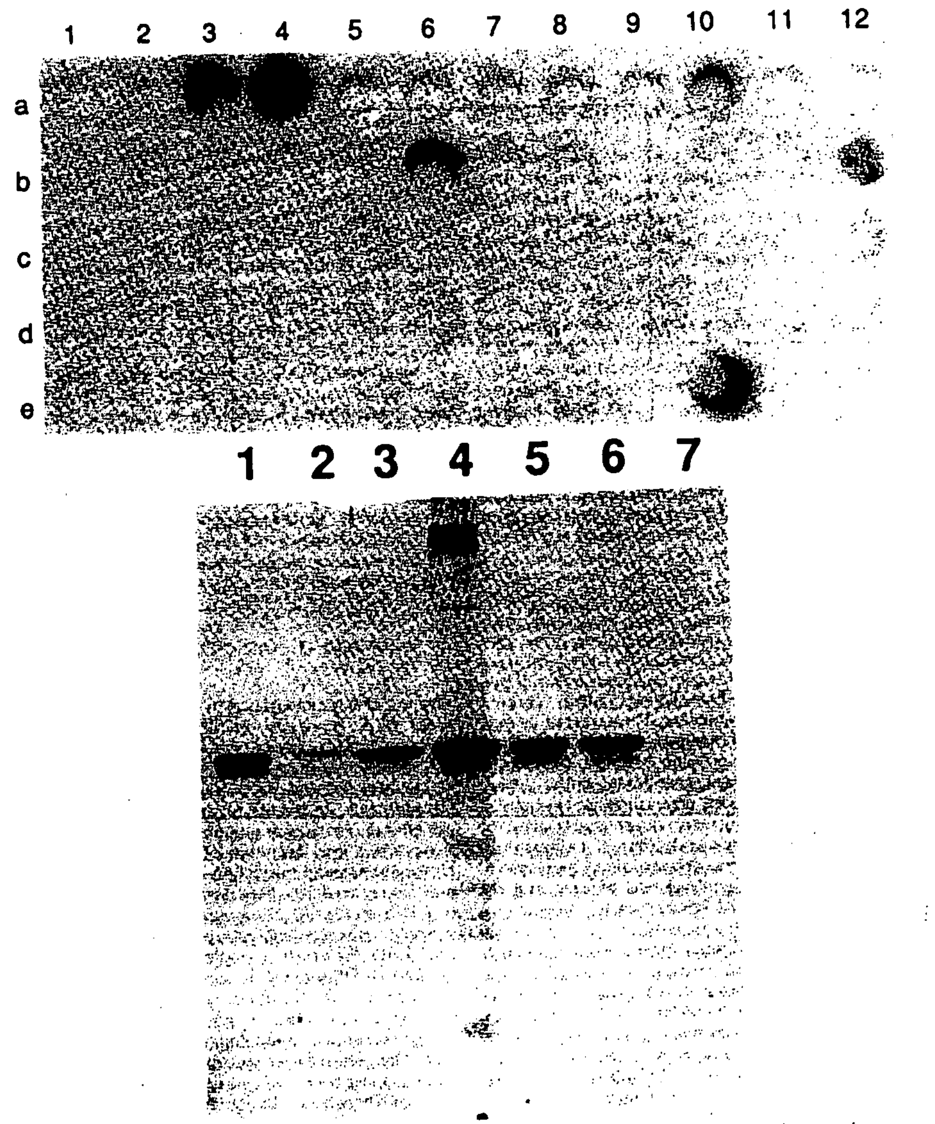

Figure 10. Screening for high copy number *Pichia* integrants. Mut$^+$ transformants of a pPIC3 vector expressing pertactin were isolated prior to screening for high copy number.[306] (A) DNA dot blot of intact whole cells which were grown in microtitre wells then lysed on nitrocellulose. Most dots correspond to single-copy transformants (e.g. a1) while some are multi-copy (e.g. a4). (B) Western blot showing variation of pertactin expression levels among transformants showing a correlation with vector copy number. Track (1) native pertactin, (2) single-copy *Pichia* transformant, (3) 13-copy, (4) 30-copy, (5) 12-copy, (6) 21-copy, (7) *S.cerevisiae* pWYG7-based vector.

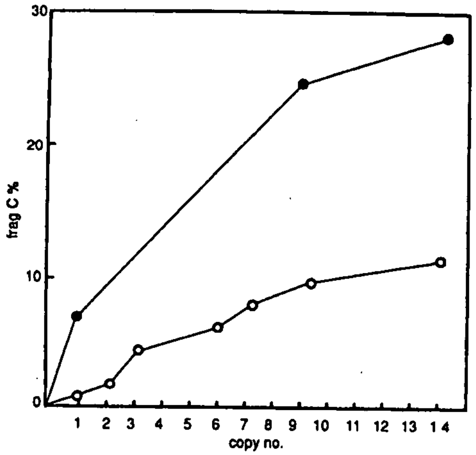

Figure 11. The correlation between gene dosage and the level of expression of tetanus toxin fragment C in Mut^s *P.pastoris* transformants. Closed circles correspond to high density inductions in the fermenter, open circles represent shake-flask inductions.

seen in Figure 11, which shows fragment C expression at varying copy number. The nature of the gene and its protein product may determine the gene dosage at which expression becomes limited. For toxic proteins increasing gene dosage will not necessarily improve yields, e.g. increasing the copy number from one to three did not result in higher levels of the secreted enzyme bovine lysozyme, although the amount of mRNA was proportionally increased.[375] Indeed, the secretion level was reduced and the enzyme accumulated intracellularly, suggesting a blockage of the secretory pathway.

In addition to efficient expression of intracellular products, *P.pastoris* is also capable of secreting high levels of foreign proteins. This was first demonstrated using the *S.cerevisiae SUC2* gene product, invertase, which accumulated to 2·5 g/l in the medium.[381] The *P.pastoris*-secreted product had much shorter N-linked carbohydrate side chains than that of *S.cerevisiae* (8–14 mannose units compared to >50). In addition, these did not contain the terminal α1,3-mannose linkages[379a] which are present in *S.cerevisiae* glycoproteins and have been shown to be immunogenic.[18] Studies of bulk endogenous glycoproteins from *P.pastoris* revealed that they are also mannosylated to a lesser extent than those of *S. cerevisiae*—about 35% of N-linked oligosaccharides having less than 14 mannose units.[149] This suggests that *P.pastoris* may be a better host for the production of heterologous glycoproteins, since extensive outer chain structures can alter the enzymic or immunogenic properties of the product (see 'Secretion of foreign proteins'). However, hyperglycosylation of certain foreign proteins secreted from *P.pastoris* has been observed (e.g. HIV gp120, C.A.S., unpublished results).

Several other proteins have been secreted at high level from *P.pastoris*, including bovine lysozyme (0·55 g/l[97]), HSA (3 g/l, K. Sreekrishna, personal communication), aprotinin (0·93 g/l[375]), hEGF (0·4 g/l[43]) and mEGF (0·45 g/l[74]). In some of these examples the corresponding signal peptide was used. The prepro leader sequence of *S.cerevisiae* α-factor has also been used, and is efficiently processed by a *KEX2* protease-like activity in *P.pastoris*.[74,375] Interestingly, Thill *et al.*[375] have reported that *S. cerevisiae* invertase is secreted by *Pichia* with much faster kinetics using the α-factor prepro sequence than with its own secretion signal. This may be an important factor in determining the gene dosage at

which secretion of a particular protein becomes limited and may also influence the glycosylation pattern of the final product (J. Tschopp, personal communication).

A problem that has occurred with several proteins secreted by *P.pastoris* is proteolytic instability in the culture medium, e.g. mEGF,[74] hEGF,[43] HSA (K. Sreekrishna, personal communication), HIV gp120 (C.A.S., unpublished results). This can be minimized by altering the pH of the culture medium upon induction (e.g. raising to pH 6·0,[74] or lowering to pH 3·0, G. Thill, personal communication), or by using a strain deleted in the *PEP4* homologue (M. Gleeson, personal communication). In the long term it would be desirable to identify the specific extracellular proteases responsible in order to construct strains lacking these activities.

An advantage of the *Pichia* system is the ease of high-density growth and scale-up without any reduction of specific productivity.[81] This feature is especially advantageous for secreted products since the concentration in the medium increases with cell density. In fact shake-flask inductions are normally sub-optimal, and there is often a large improvement in productivity using controlled fermenters[73,74,306] probably due to the high O_2 demand of the organism.

Hansenula polymorpha

The expression system developed in the methylotroph, *H.polymorpha*, is similar to that of *P.pastoris*. The gene encoding the peroxisomally-located enzyme, methanol oxidase (*MOX*), has been isolated[229] and the promoter used to express foreign genes. As with *P.pastoris AOX1*, the *MOX* gene is highly-expressed, giving methanol oxidase levels up to 37% t.c.p.,[142] and its transcription is tightly regulated. One important difference, however, is that expression of the *H.polymorpha* gene is significantly derepressed during glucose limitation or in the absence glucose, e.g. using substrates such as glycerol, sorbitol or ribose.[103,104] Thus, tight regulation of the promoter is lost in the conditions normally used for high-biomass fermentations.[137]

Transformation systems were developed using the *LEU2* and *URA3* genes from *S.cerevisiae* as selectable markers. The *LEU2* vector, YEp13, gave a low frequency of transformants which maintained the plasmid autonomously, but with low mitotic stability.[143] No integration was observed, even with linearized vector DNA, suggesting a limited homology between *H.polymorpha* and *S.cerevisiae* *LEU2* genes, although integration has subsequently been shown to occur.[348] The bacterial plasmid sequences may promote autonomous replication since the 2μ replication origin probably does not function in *H.polymorpha*.[302] The *URA3* vector, YIp5, gave a low frequency of very unstable transformants that occasionally gave rise to stable derivatives in which the plasmid had randomly integrated.[302] The transformation frequency was significantly increased by the presence of two independently isolated chromosomal DNA sequences, *HARS1* and *HARS2*, which also conferred unstable autonomous replication. Following prolonged propagation of such transformants in non-selective medium, stable *Ura*+ segregants could be isolated which contained multiple (up to 75), tandemly integrated copies of the vector. Although the mechanism of multi-copy integration is unclear, this procedure can be used to generate stable, high-copy strains for the expression of foreign proteins.[197] The use of the dominant G418-resistance marker in *H.polymorpha* has also been described.[144,197]

The *H.polymorpha* system has been used for the efficient expression and assembly of HBsAg particles containing preS2 sequences.[340] More than 95% of the protein produced could be recovered as particles, over half of which were secreted to the periplasm and could be released into the medium by inducing cells in the presence of β-glucanase. The overall yield in these permeabilized cells was several fold higher than in untreated cells, suggesting that the intracellular accumulation of particles inhibited further synthesis. Janowicz *et al.*[197] produced mixed particles containing preS1-S2-HBsAg and HBsAg by co-expression with two promoters (from the methanol-regulated formate dehydrogenase gene, *FMD*, and from *MOX*) and by selection with *URA3* and G418. Multiple integration of both genes was achieved using HARS vectors by the method described above. By obtaining strains with different copy numbers of each gene, composite particles containing various ratios of preS1-S2 and S antigen could be produced, with a total yield of 2–8% t.c.p.

The secreted plant enzyme, α-galactosidase has been produced in *H.polymorpha*.[113] The *S.cerevisiae* invertase signal sequence was used, which gave efficient secretion and was correctly processed. Attempts to isolate high-copy integrants with the YEp13-derived expression vector, by passage of transformants in non-selective medium, resulted in a strain containing two copies integrated at *MOX* and one at *LEU2*. This low integration frequency

and copy number may be because 2μ sequences prevent integration or are unstable when integrated,[348] or because the plasmid is less stable than HARS vectors and is lost before multiple integration can occur. The three-copy strain secreted 42 mg/l, which was equivalent to about 5% t.c.p. The *H. polymorpha*-derived material was over-glycosylated compared to the native enzyme and had a lower specific activity. Full activity could be restored on treatment with endoglycosidase H.

As with *P.pastoris*, *H.polymorpha* can be grown to high density (100–130 g/l), resulting in very high volumetric yields of secreted proteins. Using an integrant containing four copies of a *Schwanniomyces occidentalis* glucoamylase gene, up to 1·4 g/l of secreted enzyme was obtained.[137] The yield from an eight-copy integrant was much lower suggesting a blockage of the secretory pathway at the higher gene dosage. The secretion of several other foreign proteins in *H.polymorpha* has been reported including HSA[174], invertase and β-lactamase.[198]

Kluyveromyces lactis

K.lactis has been used in the food industry for many years in the production of β-galactosidase (lactase). Thus, its large scale cultivation has been extensively studied, and it is well accepted for the production of proteins for human use. The ability to grow on cheap substrates, such as lactose and whey, further increases its potential as a host for the production of heterologous proteins, especially for low-value products.

Transformation systems were initially developed by isolating *K.lactis* ARS sequences, since neither the *S.cerevisiae ARS1* nor 2μ replicates in *K.lactis*.[84,362] However, as with *S.cerevisiae*, *K.lactis* ARS vectors are highly unstable and are of limited use in expression systems. A number of selection markers are available for *K.lactis*, e.g. *S.cerevisiae TRP1*[84] and *URA3*,[90] *K.lactis TRP1*,[365] *URA3*[346] and *LAC4*,[84] and the G418-resistance gene.[84,362]

The two cytoplasmic linear plasmids, k1 (8·9 kb) and k2 (13·4 kb), present in killer strains of *K.lactis* have been considered as a potential vector system. They are stably maintained at 100–200 copies per cell and the regions of k1 that encode killer toxin can be deleted without affecting maintenance (reviewed in reference 364). However, their 5'-termini are covalently linked to protein, hindering manipulation *in vitro* and amplification in *E.coli*. Additionally, these plasmids encode their own cytoplasmic transcription system which does not recognize nuclear promoters. The difficulties in manipulation can be overcome by targetted integration of foreign DNA into native k1. If conventional nuclear selection markers are used, e.g. *LEU2*, this results in linear nuclear plasmids containing telomeres.[206] However, by fusing such markers to k1 promoters, recombinant linear plasmids which are cytoplasmic and stable can be generated.[207,374] It should be possible to use this system for foreign gene expression, although the k1/k2 promoters appear to be rather weak and further development, e.g. the use of the bacteriophage T7 transcription system, may be necessary.

Stable high-copy *K.lactis* expression vectors have been constructed based on the *Kluyveromyces drosophilarum* plasmid, pKD1. Although there is little sequence similarity, pKD1 is organizationally very similar to the 2μ plasmid of *S.cerevisiae*. It encodes analogous replication, amplification and segregation functions,[65] which are also active in *K.lactis*.[30] Several different types of vector based on pKD1 have been constructed which behave similarly to the analogous 2μ vectors.[30] Vectors carrying just the *cis*-acting replication element, located near one of the inverted repeats, can be maintained in host strains which have resident pKD1. However, vectors containing the entire pKD1 plasmid are significantly more stable and can be maintained in any *K.lactis* host strain.[64] The unique *Eco*R1 site adjacent to one of the inverted repeats can be used to insert foreign DNA without interruption of plasmid functions.[64] Such vectors are highly stable in pKD1° strains, even in the absence of selection, although stability is somewhat reduced in pKD1$^+$ hosts, perhaps due to incompatibility or competition. These vectors are currently used for optimal foreign gene expression in *K.lactis*.[119,120] Another reported method of producing highly stable pKD1-based vectors is to transform pKD1$^+$ hosts with plasmids containing one of the inverted repeats, in addition to the desired foreign DNA. Once introduced, these can recombine with resident pKD1 at relatively high frequency, due to the pKD1-encoded FLP recombinase, giving stable recombinant vectors.[402]

A small number of promoters have been used in *K.lactis* expression vectors. The best-characterized *K.lactis* promoter is that of the *LAC4* gene, encoding β-galactosidase, which is induced up to 100-fold by lactose or galactose. Its regulation parallels the *S.cerevisiae GAL* system, though there are significant differences: the *K.lactis GAL* genes, including *LAC4*, show no glucose repression, and the *GAL1,7* and *10* genes are only induced five- to ten-fold.[96a] Some of these differences can be ascribed

to the fact that *LAC9*, the *GAL4* homologue of *K.lactis*, is not involved in glucose repression in many strains. Several *S.cerevisiae* promoters are active in *K.lactis* and have been used for foreign gene expression, e.g. *PGK*[120] and *PHO5*.[119] In future, promoters from the recently isolated *K.lactis* genes encoding GAP[344] and alcohol dehydrogenase[324,344] may be used.

A number of studies show that *K.lactis* can efficiently secrete foreign proteins, including prochymosin which is only poorly secreted by *S.cerevisiae*. Signal peptides derived from HSA, the *K.lactis* killer toxin α-subunit, and the prepro peptides of α-factor from both *K.lactis* and *S.cerevisiae* have been used. In marked contrast to *S.cerevisiae*, prochymosin was efficiently secreted by *K.lactis* in a fully soluble, acid-activatable form, using a single-copy integration vector carrying the *LAC4* promoter.[391] Remarkably, about 80% of the prochymosin produced was secreted even when expressed without a signal peptide, though the overall level was reduced. The highest levels were obtained using the native leader peptide or the α-factor prepro sequences from either *K.lactis* or *S.cerevisiae*. The stability of the integrated expression cassette was sufficient to allow scale-up to 41,000 litres, and the product is used commercially in the manufacture of milk products.

Other heterologous proteins have been secreted using pKD1-derived vectors. Fleer *et al.*[120] described the secretion of HSA using its own secretion signal, or that of the *K.lactis* killer toxin α-subunit. The level of HSA produced was highly strain-dependent and this was largely due to differences in stability of the vector. Using the *S.cerevisiae PGK* promoter, the highest-expressing strain produced about 300 mg/l HSA in shake flasks. In high density (80–90 g/l dry weight of cells), fed-batch fermentations several g/l HSA were produced from cultures of up to 1000 litres. This system has also been used for the production of a HSA-CD4 fusion protein designed as a potential therapeutic agent for use in HIV infection (R. Fleer, personal communication).

The secretion of interleukin 1β (IL-1β) by *K.lactis* has also been reported, using the toxin α-subunit signal, either with or without the pro region derived from HSA.[119] These signal peptides were accurately and efficiently processed, but only about 20% of the product was secreted (80 mg/l in shake flasks). As in *S.cerevisiae*, the *K.lactis*-derived IL-1β was fortuitously glycosylated and largely inactive, though full activity was restored by digestion with endoglycosidase H. A mutant form of IL-1β which lacked the unique N-linked glycosylation site was also fully active. Plasmid stability was significantly reduced in IL-1β expressing cells, but this could be improved by replacing the constitutive promoter (*S.cerevisiae PGK*) with a regulated one (*S.cerevisiae PHO5*).

The glycosylation pattern of two other heterologous proteins secreted in *K.lactis* was examined by Yeh *et al.*[411] Variants of tPA and the tissue specific inhibitor of metalloproteinases (TIMP) were secreted using their own secretion signal or that of the killer toxin. In each case the secreted material was reported to be over-glycosylated and was not immunoreactive unless treated with endo H.

Yarrowia lipolytica

Y.lipolytica has been investigated for use in a number of industrial processes, including the production of a various metabolites (e.g. citric acid,[337] 2-keto glutarate,[243] erythritol,[93] mannitol,[94] isopropyl malate[92]), the bioconversion of alkanes and fatty acids into alcohol, and the production of single cell protein from *n*-paraffins.[133,163] In addition, this yeast secretes a variety of high molecular weight proteins including acid proteases,[408] lipases,[2] a ribonuclease,[66] and an alkaline extracellular protease (AEP).[377] Under optimal conditions AEP can be induced to levels of 1–2 g/l and is the major component of the culture supernatant.[377] This inherent capacity for high-level secretion, plus the ability to grow to high cell density at industrial scale, have prompted the investigation of *Y.lipolytica* as a host for heterologous gene expression.

Early studies of *Y.lipolytica* genetics were hampered by its low sporulation frequency and low spore viability. Indeed, these characteristics led to its original classification as *Candida lipolytica*, since no sexual cycle was demonstrated until 1970.[403] However, improved techniques for mating, sporulation, and ascospore recovery, combined with improved strains derived from inbreeding programmes have led to the development of a genetic map, comprising at least five linkage groups.[273] *Y.lipolytica* is a dimorphic yeast, being unicellular in minimal medium containing glucose or *n*-hexadecane, forming mycelia in minimal medium containing olive oil or casein, and giving a mixture of both forms in complex medium. Mutants which form smooth colonies containing only yeast-phase cells have been isolated[123,274] but the molecular events involved in the regulation of growth morphology are uncharacterized.

Transformation of *Y.lipolytica* was first achieved using two different selectable markers. Davidow

et al.[85] used the homologous *LEU2* gene to transform cells permeabilized by lithium acetate. Transformation occurred by integration into the chromosomal *LEU2* locus via homologous recombination. Linearization of the vector within the *LEU2* gene resulted in a 1000-fold increase in transformation frequency. Gaillardin *et al.*[135] used vectors containing random *Y.lipolytica* genomic fragments inserted into the upstream region of the *S.cerevisiae LYS2* gene for the selection of transformed sphaeroplasts. Transformants commonly contained several tandemly integrated copies of the vector suggesting that the *LYS2* gene was poorly expressed. Unexpectedly, no sequences capable of supporting autonomous replication were isolated. Wing and Ogrydziak[405] were also unable to isolate ARS sequences using a similar strategy. This was subsequently found to be because ARSs occur relatively infrequently in *Y.lipolytica*, and because plasmids containing these sequences are unusually stable.[123] Thus, such transformants were probably erroneously scored as integrants. Using mutant host strains in which replicating vectors were fortuitously less stable, Fournier *et al.*[123] isolated the *Y.lipolytica* ARS elements, *ARS18* and *ARS68*. Vectors containing these sequences were present in only 1–3 copies per cell and were very stable, being lost at a rate of 0·5–5% per generation. Since only two different ARSs were isolated, a maximum frequency of only one element per 1000 kb of genomic DNA can be calculated. These characteristics suggested that the *ARS18* and *ARS68* elements could also contain centromere function, and this has been demonstrated genetically.[133] Expression vectors based on the *ARS18* element have now been developed.[271]

In addition to *LEU2*, several other *Y.lipolytica* genes have now been cloned and used as selection markers for transformation, e.g. *LYS1*, *LYS5* and *ADE1*,[163,407] *HIS1* and *URA3*.[86] *Y.lipolytica* is resistant to many of the antibiotics commonly used for *S.cerevisiae*, including G418 and chloramphenicol, but alternative dominant selection markers have been developed. The *LEU2* promoter was fused to the phleomycin-resistance gene from Tn5 and used for the direct selection of transformants.[134] A high proportion of resistant colonies were found to be untransformed mutants, but this could be reduced by introducing an expression phase prior to plating. An alternative dominant transformation marker is the *SUC2* gene of *S.cerevisiae*, which was fused to the promoter and secretion signal sequence from the AEP gene, *XPR2*.[270] Direct selection on sucrose medium was possible, probably since most of the secreted invertase remains in the periplasm, preventing crossfeeding of untransformed cells.

The *XPR2* promoter, which is tightly regulated by pH and by carbon and nitrogen sources,[275,276] and the *XPR2* secretion signal sequence have been used to produce other foreign proteins in addition to invertase. The *XPR2* gene was independently cloned by three groups and found to encode a preproenzyme.[87,247,270] The mature protease is produced by a series of processing events which sequentially remove the presequence and two or three proregions.[247] The presequence is cleaved on translocation into the endoplasmic reticulum and, after trimming of N-terminal X-Pro and X-Ala dipeptides, the pro sequences are then cleaved by a KEX2-like activity, most likely encoded by the *XPR6* gene. Deletion analysis suggests that the proregion is required for efficient secretion of AEP.[133]

The AEP prepro sequences have been used to direct the secretion of two commercially-important proteins, bovine prochymosin[124] and porcine α-interferon.[164,271] Franke *et al.*[124] fused prochymosin cDNA to five positions within the AEP coding sequence, resulting in the expression of prochymosin fusion proteins containing the presequence alone, the preproI region, the preproIproII region, and the preproIproII region plus either 14 or 90 amino acid residues of the mature AEP. Each of these fusion proteins was efficiently secreted and released active chymosin on treatment with acid. Thus, the AEP proregion was not necessary for the secretion of prochymosin. In the case of the preproIproII fusion, the AEP secretion and processing signal sequences were shown to be accurately recognized and cleaved. Porcine α-interferon was efficiently secreted when fused to either the preproI or the preproIproII regions of AEP[164,271] although some incorrect processing was reported[133]. The final level of α-interferon secreted was increased about two- to three-fold using an *ARS18* rather than an integrating vector.[271] However, this improvement was less than the six-fold increase found with AEP since α-interferon expression resulted in reduced vector stability. Similar results were obtained for prochymosin which gave only 1·3-fold higher levels using the ARS vector. Regulation of the *XPR2* promoter was also impaired using this vector, since basal AEP levels were found to be 50-fold higher than normal under repressing conditions.

Schizosaccharomyces pombe

Aside from *S.cerevisiae*, the fission yeast, *S.pombe*, is the most intensely studied and well

characterized of the yeast species. This is largely because, like budding yeast, its life cycle and growth characteristics are particularly suited to genetic and biochemical analysis. The early development of a transformation system[22] has led to the cloning and characterization of a large number of genes, and to the development of an array of genetic manipulation techniques comparable to those used in *S. cerevisiae* (for review, see reference 319). Such studies have highlighted how distantly related these two yeasts are. In fact, sequence comparisons show that for many *S.pombe* genes, the mammalian homologues are only marginally more divergent than corresponding *S.cerevisiae* genes,[319] and some are actually less divergent (e.g. *ras*[127]). The utility of *S.pombe* in isolating mammalian genes by complementation of corresponding mutant homologues has been demonstrated,[230] and this remains the most important use of this expression system. In contrast, the use of *S.pombe* for protein production has been limited since little fermentation technology has been developed, and because relatively few inducible promoters were available.

Transformation of *S.pombe* has been described using sphaeroplasts,[22] lithium salts,[165] and electroporation.[179] A highly efficient method uses lipofectin to enhance uptake of DNA by sphaeroplasts.[5] A number of selectable markers have been described (see reference 409) but the *LEU2* and *URA3* genes from *S.cerevisiae*, which complement the *S.pombe leu1* and *ura4* mutations, are most commonly used. The corresponding *S.pombe* genes have also been used,[9,212] and dominant selection using the G418 and bleomycin resistance genes has been demonstrated.[224,323]

S.pombe expression vectors normally contain sequences derived either from the 2μ plasmid of *S. cerevisiae* or from the *S.pombe ars1*. The 2μ sequences that have ARS activity in *S.pombe* do not include the complete 2μ *ORI* and do not depend on any 2μ-encoded function.[132] These vectors have relatively low copy number (5–10 per cell) and mitotic stability (30–45% loss per generation without selection[165]). The *ars1* vectors behave similarly but have higher copy number (about 30/cell[165]). Stability and copy number of *ars1* vectors is greatly enhanced by the presence of an *S.pombe*-derived sequence called *stb*, which appears to provide a partitioning function.[165] These *ars1/stb* vectors, e.g. pFL20,[240] have a copy number of about 80 and are lost at a rate of 13% per generation.[165]

A number of promoters have been used for the expression of foreign genes in *S.pombe*. Promoters from *S.cerevisiae* genes generally function poorly, giving inefficient and aberrant initiation of transcription.[317,318] Nevertheless, the *S.cerevisiae PGK* promoter has been used to express polyoma middle T antigen,[27] and the *ADH1* and *CYC1* promoters used to produce biologically active, secreted antithrombin III.[46] In addition, the *S.cerevisiae* genes for three glycosidases (α-mannosidase, exoglucanase and endochitinase[226]) and the *Saccharomyces diastaticus* glucoamylase gene[112] have all been expressed in *S.pombe* using their respective promoters. However, the SV40 early promoter and the promoter from the *S.pombe* alcohol dehydrogenase (*adh*) gene have been most commonly used. The *adh* gene is constitutive and gives alcohol dehydrogenase levels of about 0·5–2% t.c.p.[320] With the SV40 early promoter transcripts initiate at the same position in *S.pombe* as in mammalian cells[203] although it is weaker than the *adh* promoter. Toyama and Okayama[379] used the chloramphenicol acetyltransferase gene to test a number of other mammalian promoters for activity in *S.pombe*. The human chorionic gonadotrophin α and human cytomegalovirus promoters were about ten-fold stronger than the SV40 promoter and several others, although weaker, were also functional. Other constitutive promoters that have been used are the cauliflower mosaic virus (CaMV) 35S promoter,[145,289] which gave expression levels similar to the *adh* promoter, and a promoter isolated from random *S.pombe* genomic fragments, called 54/1,[224] which gave β-galactosidase levels of 5% t.c.p.

Regulatable expression systems for *S.pombe* have also been described. One uses the promoter from the *S.pombe* fructose bisphosphatase (*fbp*) gene which is expressed at very low levels in cells grown on 8% glucose and is derepressed 100-fold in media containing non-repressing carbon sources.[176] However it should be noted that, even in 8% glucose, the *fbp* promoter is partially induced on entry into stationary phase. A second regulated system uses mammalian glucocorticoid response elements to drive expression. These are induced up to 70-fold by glucocorticoid hormones when the hormone receptor is co-expressed.[287] The fully-induced expression level was about 20% of that using the *adh* promoter. A promising regulated system uses the promoter from a highly-transcribed *nmt1* gene which is strongly repressed by thiamine.[249] This was used to regulate a multi-copy chloramphenicol acetyltransferase (CAT) reporter gene, and gave a 200-fold thiamine-dependent repression of CAT expression.

In addition to the examples already described above, a diverse selection of other heterologous

proteins have been expressed in *S.pombe*. The human liver microsomal enzyme, epoxide hydrolase, was expressed in an active form that could be isolated from *S.pombe* microsomal fractions.[192] Active factor XIIIa was produced at 2 mg/l using a high copy number, *adh* expression vector derived from pFL20.[45] The expression of functional single-chain antibody molecules capable of binding their cognate hapten, the aromatic dye fluorescein, has been described.[88] Jagadish *et al.*[194] expressed the large polyprotein of infectious bursal disease virus, which was processed to give stable VP3 protein. Strasser *et al.*[368] expressed the α-amylase gene from *Schwanniomyces occidentalis*. The bacterial proteins, β-glucuronidase,[289] xylose isomerase[58] and bacterio-opsin[166] have also been produced in *S.pombe*. The latter is correctly processed by cleavage at the N-terminus, is inserted into membranes, and forms photoactive bacteriorhodopsin pigment when cells are grown in the presence of its chromophore, retinal.[166] Another integral membrane protein expressed in active form by *S.pombe* is the glucose transporter from *Arabidopsis thaliana* encoded by the *STP1* gene.[329]

The secretion of foreign proteins is a relatively unexplored area of potential interest since, like higher eukaryotes, *S.pombe* is known to galactosylate glycoproteins (e.g. invertase,[263] acid phosphatase[93]). However, *S.cerevisiae* invertase was not galactosylated when expressed in *S.pombe*,[263] and both this protein and homologous ones are highly glycosylated. In addition, antithrombin III was hyperglycosylated when secreted by *S.pombe*.[46]

PHYSIOLOGY OF FOREIGN GENE EXPRESSION

High-level expression of a foreign gene can place a significant metabolic burden on the host cell, reducing its growth rate and affecting the efficiency of gene expression. Expression of some genes causes a more acute effect, either through a severe effect on metabolism or by direct toxicity. In constitutive systems where growth and expression are linked there is then strong selection for cells with reduced foreign gene expression, so that low-expressing variants arise. Variants may also be selected without growth, for example through effects of the product on cell viability during freezing or long-term storage on agar. Therefore it is highly desirable to use tightly-regulated promoters where the growth and induction phases can be largely separated. This is particularly important with large-scale fermentations where growth is over many generations. With regulated systems only highly toxic products should be problematic, because of their ability to rapidly affect host cell metabolism.

Mechanisms of toxicity

Toxicity is diagnosed by a difficulty in obtaining transformants with constitutive expression vectors or a reduction in growth rate when regulated vectors are induced. Which metabolic process is predominantly affected depends on the foreign gene and vector system. The maintenance of ultra-high-copy 2μ/*LEU2*-d plasmids alone is sufficient to reduce the host cell growth rate,[397,169] whereas no effect would be expected with integrated vectors. Multi-copy promoters may compete for transcription factors and inhibit expression of co-regulated genes: thus multi-copy *GAL7* vectors inhibit *GAL10* gene transcription, and could affect galactose metabolism.[14] High levels of mRNAs containing rare codons could deplete cognate tRNAs and inhibit the translation of host mRNAs containing rare codons. This appears to be the effect of *lacZ* mRNA in yeast, which at high levels is toxic, especially during growth on minimal medium.[292]

Toxicity is a relatively common problem with secreted proteins, especially complex ones. This may be due to the complexity of the secretory pathway, offering a number of possible bottlenecks, or else to the possibility that foreign secreted proteins may be frequently malfolded and cause a blockage in the pathway. Examples of highly toxic secreted proteins are tPA,[169] IGF-1,[343] EBV gp350.[335] In the case of tPA, acid phosphatase secretion is reduced, suggesting a general block in secretion. Membrane proteins, e.g. *E.coli ompA*,[196] influenza virus haemagglutinin,[191] polyoma virus middle T antigen,[27] are particularly likely to be toxic, possibly due to non-specific insertion and disruption of yeast intracellular membranes. This may be the mechanism of toxicity of HBsAg, since constitutively-expressing strains have reduced viability on freezing and thawing (M.A.R., unpublished results).

Certain proteins have specific, acutely toxic effects. As an extreme example, induction of intracellularly expressed A-chain of ricin instantaneously kills yeast cells, and this has been used as a selection for non-toxic A-chain mutants.[125] Over-expression of proteases, such as HIV-1 protease, may be toxic. Mammalian transcriptional *trans*-activators are frequently toxic, presumably through their ability to sequester components of the yeast transcriptional apparatus.

A number of approaches can be used in an attempt to overcome product toxicity. Secretion may be used to segregate the product from the site of toxicity even if it is not normally secreted, e.g. HIV-1 protease.[288] Alternatively, fusion to other proteins may inhibit biological activity and toxicity. The approach of selecting for mutants resistant to toxicity has been used successfully with IGF-1.[347] Toxin-resistant mutants have been used to express diphtheria toxin fragment A, which normally kills yeast cells, and chimaeric diphtheria toxins.[285]

Generation of low-expressing variants

To a certain extent it is possible to limit the generation of variants having reduced expression levels, which can arise with constitutive systems. The most common response to toxicity with 2μ vectors is reduced copy number, which can reach a level as low as 1 per cell even with selection.[35] However, when *LEU2*-d selection is used the drop in copy number that can occur without affecting growth is limited, and other mechanisms such as structural rearrangement predominate. Where the selection marker is flanked by 2μ DNA, recombination can result in its transfer to native 2μ with loss of the expression cassette.[99] One way of preventing this is by using plasmids such as pJDB219 in 2μ-free strains.

Another mechanism for plasmid loss involves homologous recombination between the selection marker and chromosomal allele to generate a prototroph. This can be prevented by using a host strain with a deletion in homologous chromosomal sequences or by use of recombination-deficient mutants (e.g. *rad52*[244]).

An unusual plasmid mutation was observed during the constitutive expression of polyomavirus middle T antigen.[27] Transformants grew very slowly, and there was either plasmid loss or spontaneous generation of plasmids expressing a truncated antigen, which lacked the membrane-spanning domain and was non-toxic. Mutant plasmids arose by deletion of one G.C base pair in a run of nine, causing a frame-shift 5' of the DNA encoding the hydrophobic region.

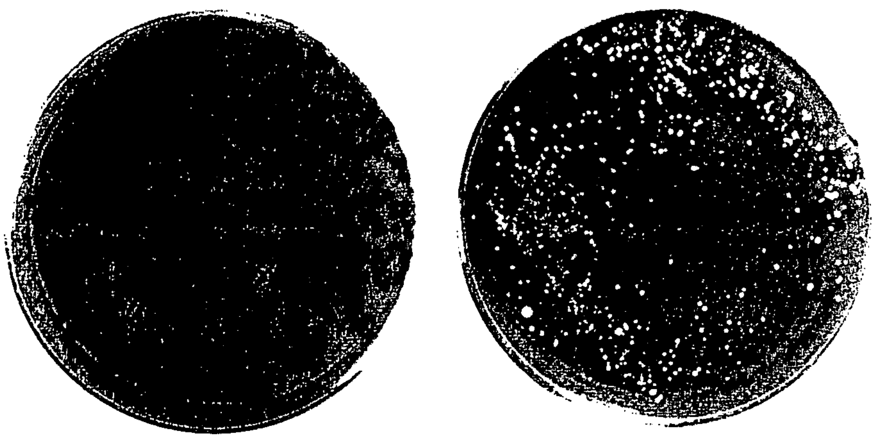
We have observed an example where a mutation in a host cell gene inactivated the promoter used in the expression vector. The system was a *PHO5* vector expressing HBsAg in a constitutive *pho80* background (M.A.R., unpublished results). Mutant non-expressing cells were enriched during freezing and thawing of stock cultures, and out-grew the expressing cells in fermenters, resulting in greatly reduced product yields. Mutant cells were detected using a chromogenic plate assay for secreted acid phosphatase expressed from the chromosomal *PHO5* gene (Figure 12). The problem was eliminated by a combination of measures: (i) using a freezing protocol which gave higher viability to reduce enrichment of mutant cells and (ii) plating out stock cultures and using the plate assay to monitor for non-expressing colonies. The mutants did not arise at detectable frequencies without the enrichment that occurred during low-viability freezing. This example illustrates the type of problem that can occur on scale-up of a constitutive system expressing a mildly toxic product.

Large-scale fermentation and optimization

In the development of a large-scale industrial fermentation process, the first step is transfer to small fermenters. These offer the possibility of controlling a number of culture parameters, resulting in much greater reproducibility and the ability to reach very high cell densities. However, a significant effort is frequently required in order to maximize product yield, though in theory it should be possible to control conditions so as to give higher yields than in shake-flasks. High-density fermentation is generally desirable in order to minimize capital expenditure on fermentation equipment; it is particularly valuable with secretion, where the concentration of secreted protein in the medium can increase almost proportionately to cell density.[213]

In the case of recombinant *S.cerevisiae*, glucose is almost always used as the carbon-source. The two extremes of glucose-utilization are fermentation, which yields ethanol as a by-product, and respiration, which is much more efficient for conversion to biomass. However, growth to high density on glucose is problematic since *S.cerevisiae* has a limited capacity to metabolize glucose oxidatively, accumulating ethanol, which eventually inhibits growth, above a specific growth rate of 0·2 to 0·25 h^{-1}.[117] Secondly, glucose concentrations above approx. 0·1% repress respiration.[298] In aerobic batch cultures, such as shake-flasks, growth on glucose is diauxic: the glucose is rapidly fermented to ethanol and CO_2, and the ethanol is metabolized in a second growth phase once the glucose is exhausted.

In order to prevent the conversion of glucose to ethanol and maximize biomass, bakers' yeast is grown using a fed-batch process: molasses and nutrients are slowly fed to the fermenter, the feed rate increasing as the cell density increases, so as to obtain



A B

Figure 12. Accumulation of non-expressing cells during fermentation of an *S.cerevisiae pho80* strain containing a *PHO5* vector for HBsAg expression. Samples were taken at the end of 10 litre fermenter runs of the constitutively-expressing strain, plated on non-selective agar and assayed for secreted acid phosphatase (Pho phenotype) by overlaying with agar containing a chromogenic substrate. (A) High-yield fermenter run contained Pho⁺ cells only. (B) Low-yield run contained a high proportion of Pho⁻ cells in which the *PHO5* promoter is inactive. Low-yield runs resulted from enrichment of mutant non-expressers during low-viability freezing. Improved freezing protocols resulted in high-yield runs.

an almost constant specific growth rate. Similarly, fed-batch using calculated glucose feed rates has been used for high-density culture of recombinant *S.cerevisiae*.[151,182] More refined methods have also been applied: computer control has been used to couple glucose feed rate to respiratory quotient (RQ = CO_2 evolved/O_2 consumed; maintained at 1·0 to 1·2) using on-line gas analysis,[118,213,384] or to ethanol concentration using a biosensor,[3] resulting in cell densities of 80 to 200 g/l dry mass. These results have been achieved with semi-synthetic media containing protein hydrolysate (casamino acids) or yeast extract.

With an ideal tightly-regulated system, biomass accumulation would be separated from foreign protein induction, and the two could be optimized separately. In constitutive systems this is clearly not possible, but even with regulated systems a combined growth/induction process must usually be developed. We will illustrate some principles of process development by referring to *S.cerevisiae* systems using three types of promoters: constitutive glycolytic, glucose-repressible, and galactose-inducible.

As described above, product toxicity is a serious problem with constitutive systems: Fieschko *et al.*[118] found severe plasmid-loss using a *PGK* vector expressing γ-interferon, and were unable to achieve high cell densities. However, an optimized process has been developed for secretion of pro-urokinase from a super-secreting *pmr1* strain using the *PGK* or *TPI* promoters.[384] Accumulation of secreted product was growth-associated but was not as high in an RQ-controlled fed-batch culture (77 g/l dry mass) as in a perturbed batch fermentation (45 g/l), where glucose was pulsed into a batch culture. This difference may be due to activation of glycolytic promoters by high concentrations of glucose. In batch fermentations the secretion of human lysozyme, using the enolase promoter, was increased four-fold by increasing starting glucose concentration from 2 to 10%, even though growth was unaffected.[185] In view of these observations another approach would be to use glycolytic promoter systems in two-stage fermentations, an initial glucose-limited stage for biomass accumulation followed by an increased glucose feed for induction.

Glucose-repressible expression systems present problems because of the conflicting requirement to maintain high glucose in order to repress the promoter, and to limit glucose in order to maximize biomass. However, a fed-batch process for the production of a SOD-proinsulin fusion protein using a *GAP/ADH2* promoter has been developed, though the cell density achieved was only 30 g/l.[378] Initial experiments indicated that a glucose excess was important to repress the promoter and maintain plasmid stability. Quite high yields of product (>0·5 g/l) were obtained in simple batch cultures with glucose concentration starting at 5%, but biomass was low. A fed-batch procedure was developed using a constant, empirically-determined glucose feed which led to glucose excess during most of the growth phase but to very low glucose at later stages as the cell density increased. Sub-optimal feed-rates would have resulted either in plasmid loss or in incomplete induction. Apparently the residual glucose (20 mg/l) was partially repressing, since changing from glucose to a final ethanol feed yielded a two-fold improvement to 1·2 g/l of product (increasing to 1·6 g/l at 26°C).

The first published study of galactose induction in a high-density fermentation involved the expression of γ-interferon using the *GAP/GAL* hybrid promoter.[118] Although biomass yields of 200 g/l were possible using RQ-controlled glucose-limited fermentations, biomass was restricted to <100 g/l because of O_2-transfer limitation. Three induction methods were compared: (i) 10 g/l pulses of galactose, (ii) replacement of the glucose feed by galactose, (iii) (i) followed by (ii). The third method gave the highest yields and this was rationalized as being due to the partial induction of galactose-metabolizing enzymes during galactose pulsing, preventing temporary carbon-source starvation on switching the feeds. However, in another study galactose was rapidly metabolized in glucose-limited cultures.[3] A further improvement (to 2 g/l of product) was made using a diploid host strain, however the yield of γ-interferon was only 3 to 5% t.c.p. compared to 10% in shake-flasks.

More recently, the production of β-galactosidase was examined using a galactose-inducible, hybrid *CYC1/GAL* promoter.[3] It was found that galactose added to glucose-limited cultures was rapidly metabolized and depleted, since the cells were derepressed, and it was preferable to feed a glucose/galactose mixture so that glucose was preferentially metabolized. In this way β-galactosidase was induced to 7% t.c.p. at a cell density of 100 g/l; addition of a final 50% galactose feed increased the yield to 8%, considerably higher than the level in shake-flasks.

Expression systems based on several yeasts other than *S.cerevisiae* have been scaled-up. A recombinant *K.lactis* strain expressing secreted HSA under the control of the *S.cerevisiae PGK* promoter has been grown to high density (80 to 90 g/l) using glucose-limited fed-batch at the 1000 l scale, yielding HSA at several g/l.[120] A commercial process for the secretion of prochymosin has been scaled-up to 41,000 litres.[391]

P.pastoris is particularly suited to high-density culture and can be grown to >100 g/l on simple defined media containing glycerol without the need for complex fed-batch procedures.[80] The tight regulation of the *AOX1* expression vectors means that the growth phase is identical for different protein products, and scale-up to large fermenters does not affect biomass or product yield.[80] Additionally, contrary to the experience with *S.cerevisiae*, an immediate improvement in percentage yield of foreign protein is generally seen on going from shake-flasks to fermenters.[73,74,306] This appears to be due, at least in part, to the high O_2-demand of the organism, which is not satisfied in shake-flasks.

Figure 13 shows the results of a high-density fermentation using a *Pichia* Mut[s] recombinant containing 14 integrated copies of a tetanus toxin fragment C expression vector.[73] The culture was started with an initial batch growth in glycerol; when this was used up a slow glycerol feed was initiated, during which growth was glycerol-limited and the *AOX1* promoter derepressed, allowing rapid induction during the subsequent methanol feed. Most of the growth occurred during the glycerol feed; product accumulated for about 30 h into the methanol feed, during which time there was no cell doubling, reaching a level of 27% t.c.p. (*cf.* 10% in shake-flasks) or approx. 12 g/l. In contrast, Mut^+ strains continue to grow rapidly during the methanol feed and are fed methanol at a higher rate. Using similar protocols high levels of several commercially-important proteins have been achieved: e.g. SOD (1·3 g/l[375]), HBsAg (0·4 g/l[81]), tumour necrosis factor (10 g/l[360]), *Bordetella pertussis* pertactin (3 g/l[306]), secreted HSA (3 g/l; K. Sreekrishna, personal communication), secreted EGF (0·45 g/l;[74] G. Thill, personal communication). Mut^+ strains can also be grown in continuous culture to increase fermenter productivity.[97]

Apart from the growth and induction protocols, a number of other variables have been found to affect yields and should be looked at systematically. Lower temperatures may increase yield by reducing proteolysis.[378] Added phosphate in the medium has increased heterologous secretion in at least two

b)

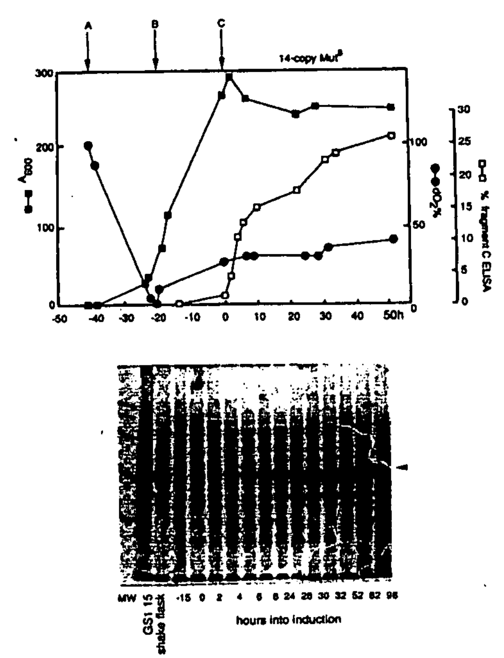

Figure 13. Fermentation of a 14-copy *Pichia* Mut^s transformant expressing tetanus toxin fragment C. (a) Cell density (A_{600}), dissolved oxygen (dO_2), and fragment C as per cent of cell protein are plotted against time (0 h = start of induction). Fermentation conditions were as described elsewhere.[73] Timepoint A, addition of shake-flask inoculum, B, glycerol-limited feed, C, methanol feed. (b) Coomassie blue-stained SDS polyacrylamide gel showing protein extracts from cells taken at different times during induction. The arrow indicates the position of fragment C. For comparison, a sample from the same transformant induced for 48 h in a shake flask is shown in lane 3, and extract from an untransformed control strain is shown in lane 2.

cases.[114,384] Buffering to high pH with *S.cerevisiae*[384] and high or low pH with *P.pastoris*[74] (K. Sreekrishna, personal communication) has reduced proteolysis of secreted proteins. Increased growth rate increases plasmid stability and can result in greater product yield.[82] Finally, different strains of *S.cerevisiae* may have dramatically different growth and induction properties.

CONCLUDING REMARKS

In its early stages the use of yeast for heterologous expression was highly favoured due to the obvious advantages of a microbial eukaryotic system. However, interest waned with the discovery of unforseen problems and with the advent of powerful alternative systems such as baculovirus. Yeast expression

systems are now in a period of resurgence, for a number of reasons. One of the major disadvantages compared to *E.coli* and baculovirus has been the generally lower yield of product, frequently due to the difficulty in obtaining high-level transcription of foreign genes. This problem has now been addressed in *S.cerevisiae* in a number of ways: for example, by over-expressing transcriptional *trans*-activators (e.g. with *ADH2*[291]), by constructing glycolytic promoters with superimposed regulation,[398] and by random screening for super-expressing mutant strains.[354] The use of yeasts such as *Pichia pastoris*, which naturally have powerful, tightly-regulated promoters, has provided an alternative solution. Table 6 (see 'Expression in non-*Saccharomyces* yeasts) shows data for two proteins produced in four expression systems, *S.cerevisiae, P.pastoris, E.coli* and baculovirus, illustrating the comparative strength of the *P.pastoris* multi-copy *AOX1* vector system. Another factor has been the accumulation of experience in the high-density growth and induction of recombinant yeasts, comparing favourably with the difficulties encountered in scaling up other eukaryotic systems. *Pichia* is particularly suited to scale-up and should continue to become more widely used for industrial production.

A number of other areas have shown significant advances, for example the development of more stable 2μ vectors, of rDNA and *Ty* multi-copy integrating vectors, and the use of autoselection markers. The development of episomal vectors for *Kluyveromyces lactis* is also worthy of mention since this yeast appears to be particularly efficient in secretion. However, there are areas where improvements are needed. In *S.cerevisiae* it appears that foreign genes are frequently poorly transcribed using certain promoters, possibly due to a requirement for intragenic yeast sequences (DASs) for maximal transcription. Unfortunately, it is not clear how general the problem is, nor is there yet direct evidence for DASs. In *P.pastoris* there appears to be no such problem using the *AOX1* promoter since very high levels of foreign transcripts can be obtained with multi-copy integrants.[73]

Despite several important successes in secreting proteins, especially unglycosylated polypeptides, this is an area which can present problems. It is still not clear why some foreign proteins are not correctly folded and transported. The current rapid progress in our understanding of protein folding and chaperones may eventually provide explanations and possibly solutions. Recently, however, the most progress in increasing yields of secreted proteins has been made using the powerful empirical approach of random mutagenesis and screening. The secretion of pharmaceutical glycoproteins remains problematic due to the differences in glycosylation between yeast and mammals. Even glycoproteins which are not hyperglycosylated contain antigenic mannose linkages: an engineered strain which could overcome this problem has been reported,[353] though no results on product antigenicity are available yet. An alternative possibility is *P.pastoris* which does not appear to add the antigenic α1,3-linked terminal mannose.[379a] The production of glycoproteins for non-pharmaceutical use, e.g. glucoamylases and xylanases, has been highly successful and presents no such problems.

In the last few years there have been many successes in the production of therapeutic proteins from yeast, for example the recombinant subunit vaccine against hepatitis B virus, human proinsulin, EGF, HSA, etc. There have also been developments in the food industry, such as the experimental use of recombinant yeast secreting glucoamylase in brewing,[157] and the production of chymosin from *K.lactis*.[391] However, in future the requirements of an expression system may be increasingly to provide reagents for research and drug discovery rather than in the production of therapeutic agents. For rapid isolation of such products it may be advantageous to make use of fusion proteins or 'tags' which allow simple affinity purification: a variety of systems are now available.[341,351] Since many pharmacological target proteins may be toxic when expressed to high levels, or may have short half-lives, it may be necessary to accept low yields and concentrate products using an affinity tag.

A highly significant development has come from the realization that many pharmacological target proteins can function in yeast cells *in vivo*. It has been reported that adrenergic receptors can be expressed in yeast and coupled to the signal transduction pathway for α-factor; using a *lacZ* reporter fused to the α-factor regulated *FUS1* promoter, a colorimetric assay that could be used for drug screening was developed.[214] There is intense commercial interest in such systems because of their advantages over mammalian cells in setting up robust drug screens, but there is scope for improvement at present. Other examples of systems that have been or could be used for *in vivo* pharmacological screening are: HIV translational frameshifting,[404] HIV TAT *trans*-activation,[100] steroid receptor binding and *trans*-activation.[293,332]

Finally, yeast expression technology is now important in the genetic analysis of organisms whose genetics are less well developed. A number of mammalian genes have been isolated by their ability to complement mutant yeast homologues, e.g. the human homologue of the *S.pombe cdc2* gene.[230] *S.pombe* may frequently be more suitable than *S.cerevisiae* for screening human cDNA expression libraries because of its closer phylogenetic relationship, and because mammalian expression vectors using the SV40 promoter are active in *S.pombe*.

XII. SUMMARY 392

ABSTRACT: The specificity of protein targeting processes is the basis of maintaining structural and functional integrity of the cell, enabling the various subcellular compartments to carry out their unique metabolic roles. Studies in plants have progressed markedly in the last 5 years, and many of the specific signals involved in the transport and targeting of proteins to the nucleus, chloroplast, mitochondrion and microbody, and to organelles along the secretory pathway (endoplasmic reticulum [ER], Golgi complex, and vacuole) have been characterized. Exciting prospects include the identification of receptors involved in the recognition of protein targeting signals, mechanisms of vesicle targeting, and the role of mRNA targeting. Although important exceptions exist, a striking feature of the mechanisms and cellular machinery of protein targeting is their universality — among plants, animals, and eukaryotic microorganisms — and even between prokaryotes and eukaryotes. More information is required about the structural features of proteins that allow for their stable accumulation in a particular subcellular compartment, of particular interest to the plant genetic engineer. Our understanding of the rules that govern protein folding and oligomer assembly and how these processes relate to a protein's ultimate stability in the cell is limited.

KEY WORDS: protein targeting, protein folding, protein assembly, protein stability, secretory pathway, molecular chaperone.

I. INTRODUCTION

A recent focus of considerable study in the field of plant cell biology is the elucidation of the molecular mechanisms involved in the intracellular transport and targeting of proteins from their site of synthesis to their final destination. The eukaryotic cell must utilize mechanisms to ensure the faithful expression of genetic information at the level of functionally and correctly localized proteins. These posttranslational controls may be imposed at several steps between synthesis of proteins on cytosolic (or organellar) polyribosomes and their final localization and functional configuration within the cell. With the exception of a few proteins of chloroplasts and mitochondria, all proteins are synthesized on free or bound polyribosomes of the cytosol, and so must be transported to, or across, one or more membranes to reach their final subcellular location. Some very fundamental questions concerning these regulatory events are being addressed in plants. For example, what is the nature of the signal and sorting machinery that target proteins to different compartments of the cell? What are the mechanisms of signal "decoding" and of protein insertion into, or translocation across, the target membrane? What are the posttranslational modifications involved in protein maturity and the acquisition of a stable three-dimensional conformation? Also, what determines the half-life of a protein in a particular cell type? The maintenance of correct intracellular targeting of proteins is likely to be particularly challenging in plants in which there is an additional organelle — the chloroplast — requiring extensive protein traffic from the cytosol and a high degree of cytoarchitecture to carry out its functions.[1] But the importance of the specificity of these processes to the cell cannot be underestimated because it is the very basis of maintaining structural and functional integrity, enabling the various compartments of the cell to carry out their diverse metabolic roles.

The focus of this review is on the various mechanisms involved in correct protein targeting in plant cells as well as some of the experimental approaches used to elucidate these events. Recent information on the mechanisms of protein targeting into and within the chloroplast, mitochondrion, peroxisome, glyoxysome, and nucleus will be covered as well as the targeting of proteins to organelles of the secretory system. Some examination of the components involved in the posttranslational modifications of proteins as well as the structure/architecture of the secretory pathway are reviewed; these topics have also been covered in recent reviews.[2-4]

Much progress has been made in recent years in the area of protein transport and targeting in plant cells. However, many of the mechanistic details concerning related events (e.g., protein translocation and vesicle targeting) remain to be elucidated. Thus, where appropriate, reference is made to analogous mechanisms in other eukaryotic organisms, with the awareness that these "heterologous systems" may not fully reflect the processes in plants.

Plant genetic engineers have endeavored to manipulate metabolic pathways to improve plant productivity and to engineer seed crops with

greater nutritional value or protein content. With respect to the latter, this has taken the form of attempts to enhance gene transcription and mRNA stability, or translatability. More recently, a novel strategy has been toward enhancing protein stability and the "mis- or "retargeting" of proteins into different subcellular compartments. Some of these studies are discussed.

II. PATHWAYS OF PROTEIN TRANSPORT IN PLANT CELLS

Major targets of protein transport in plant cells include the chloroplast, the mitochondrion, the nucleus, and the peroxisome/glyoxysome (Figure 1).[5] Proteins destined for these organelles are translated on "free" polyribosomes of the cytosol; concurrently, or shortly thereafter, they are imported into the appropriate organelle by direct recognition of specific targeting signals. In contrast, transport to the vacuole and cell surface occurs along the endomembrane system (the endoplasmic reticulum [ER], Golgi apparatus, and transport vesicles); proteins destined for this so-called "secretory" pathway are synthesized on polyribosomes associated with the ER and enter a common "gateway" by first translocating across the membrane of the ER into the lumen (Figure 1). The organelles of the secretory pathway are functionally connected by vesicular traffic; proteins move along this intercommunicating system in the lumen or in the membrane of vesicles that form from one compartment and fuse to the next compartment. The major route of transport is from the ER to the Golgi complex and from there to the vacuole or to the cell surface (plasma membrane, cell wall, or extracellular space). Thus, the protein composition of the ER and Golgi complex includes both permanent residents as well as proteins *en route* to their final destinations.

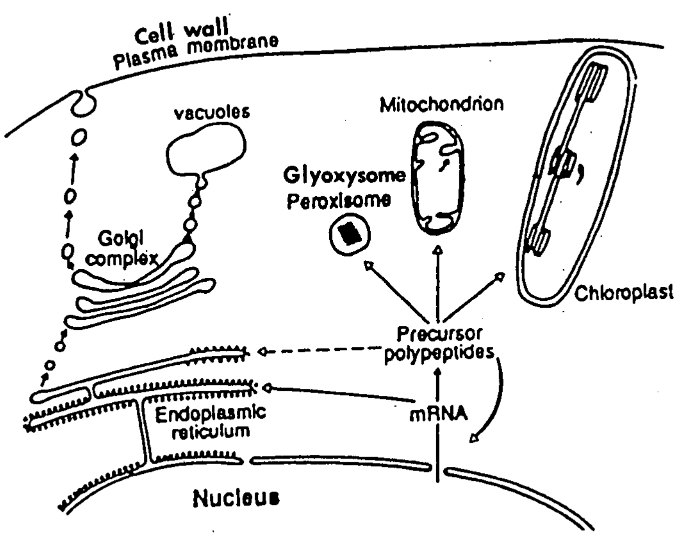

FIGURE 1. The major pathways of protein transport within the plant cell. Based on Verner, K. and Shatz, G., *Science*, 241, 1307, 1988. (With permission from the American Association for the Advancement of Science.)

III. GENERAL PRINCIPLES OF PROTEIN TARGETING

Our understanding of the mechanisms of protein targeting is far from complete, particularly within plants, but present knowledge suggests that some general principles apply:

1. Targeting information resides in the protein itself. It may be in the form of a discrete signal (e.g., a specific stretch of contiguous amino acids located internally or at the extreme end of the protein) (Figure 2A).[6] Often only the general features of targeting signals are conserved across a group of proteins targeted to the same organelle (i.e., there is no strict primary consensus signal). Thus, the secondary or tertiary structural features of the signal may be recognized by the targeting machinery. Discrete signals are also often context dependent, that is, the topogenic information must be accessible to the targeting machinery involved in its recognition. Less common than discrete signals are topogenic sequences referred to as signal patches; these targeting signals are formed from noncontiguous regions or domains of the polypeptide chain that are brought together in the folded protein (i.e., they are conformation-dependent) (Figure 2B). A single protein may have multiple targeting signals. In some cases these are distinct. However, they can be overlapping and, moreover, their functions may be affected by covalent modifications such as phosphorylation.[7] Quite different signals (and transport pathways) may serve to target proteins to the same organelle, an example being those responsible for directing proteins to plant vacuoles.
2. Several factors may influence the accuracy and efficiency of protein targeting. For example, the localization of mRNAs to specific subcellular regions or compartments

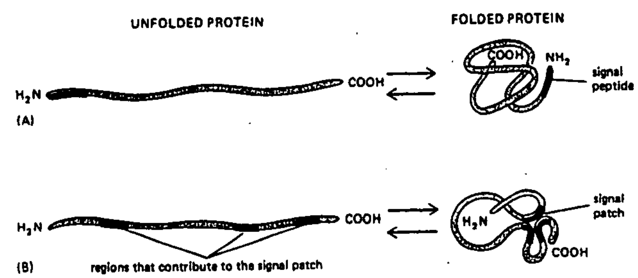

FIGURE 2. Two ways that targeting signals can be organized in proteins. (A) The signal is in a single discrete stretch of amino acid sequence that is exposed in the folded protein. These signals often occur at the end of the polypeptide chain (as shown), but they can also be located elsewhere. They are normally detected experimentally by their effect on the intracellular sorting of other proteins when they are attached to them by recombinant DNA methods (see Figure 3). (B) A signal patch can be formed by the juxtaposition of amino acids from regions that are physically separated before the protein folds (as shown); alternatively, separate "patches" on the surface of the folded protein that are spaced a fixed distance apart could form the signal. In either case, the transport signal depends on the three-dimensional conformation of the protein. For this reason it is very difficult to locate this type of signal precisely. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 2nd ed., Garland Publishing, New York, 1989. With permission from Garland Publishing.)

provides an important mechanism for targeting proteins to the sites where their activity is required.

3. Targeting sequences are probably recognized and "decoded" by specific protein receptors; interactions with lipids of the membrane bilayer may also be important, perhaps playing a facilitory role in the initial binding process to receptors on the target membrane.
4. The types of signals ("topogenic" sequences) involved in protein targeting are limited and can be classified on the basis of the nature of the target membrane and, in some cases, on the mechanism of membrane translocation or integration (e.g., involvement of specific protein effectors). Examples are signal sequences, stop-transfer sequences, retention sequences, and sorting sequences.[8] Not all membranes are translocation-competent and most translocate only specific proteins.[5] **Signal** sequences initiate translocation of proteins across specific cellular membranes; they interact with protein receptors/translocators, which effect unidirectional translocation. **Stop-transfer** sequences interrupt the translocation process that was previously initiated by a signal peptide and yield integration of proteins into translocation-competent membranes. Multiple start-and-stop transfer sequences can result in integral membrane proteins that span the bilayer multiple times.[6,9-11] **Retention** sequences function to retain proteins in certain compartments, such as the ER. **Sorting** sequences act as determinants for post-translocational traffic of subpopulations of proteins, originating in translocation-competent donor membranes (and compartments) and going to translocation-incompetent receiver membranes (compartments). For example, sorting signals direct proteins along branched pathways such as that encountered at the *trans*-Golgi network (TGN), where proteins have different transport fates after having shared a common route through the ER and Golgi complex (Figure 1; see later discussion). **Insertion** sequences may initiate unilateral integration of proteins into the lipid bilayer without the mediation of a distinct protein effector.[8] Some examples of specific targeting signals of eukaryotic proteins that fall into the major categories of topogenic sequences are presented in Table 1.[10]
5. The mechanism of protein translocation across the target membrane may involve interactions of a variety of cytosolic and membrane components; it often requires an unfolded or "loosely folded" conformation of the protein undergoing translocation, the maintenance of which may involve assistance by another protein.
6. In most cases, but by no means all, the targeting signal is transient and cleaved following protein translocation; however, this step is generally not an obligatory component of the targeting/translocation process per se.
7. Proteins fold into their final three-dimensional structure (and in some cases, assemble into oligomers) shortly after translocation is completed; often these processes are assisted by a general group of proteins termed "molecular chaperones."
8. Although important exceptions exist, a striking feature of our understanding of the mechanisms of protein targeting is their universality — among animals, plants, and eukaryotic microorganisms and even between prokaryotes and eukaryotes.

IV. GENERAL METHODOLOGY TO STUDY PROTEIN TARGETING

Various methods have evolved over the years to study protein targeting in eukaryotic cells. Current approaches commonly involve the application of recombinant DNA techniques to engineer genes (e.g., to effect specific mutations or deletions in a given gene, or to construct chimeric genes). Transfer and expression of these modified genes in host cells or organisms allow the subsequent analysis of protein targeting in a heterologous environment (e.g., the subcellular localization of the genetically engineered proteins). In addition, where isolation and preservation of in-

TABLE 1
Examples of Targeting Sequences on Eukaryotic Proteins

General type of topogenic sequence	Targeting event	Specific signal
Signal sequences	Translocation into ER lumen (signal peptide)	+ 0 0 0 0 + MKWVTFLLLLFISGSAFS^RGVF
	Chloroplast (stroma) targeting (transit peptide)	00 00 +00 0++0 0 0 0 + + MAPAVMASSATTVAPFQGLKSTAGLPVSRRSGSLGSVSNGGRIRC^M-
Stop-transfer sequences	ER stop-transfer sequence	+00 0 + + -KSSIASPFFIIGLIIGLFLVLRVGIH-
Retention sequences	ER retention sequence (soluble protein)	+-- -KDEL
	ER retention sequence (membrane protein)	++0 --++ -RRSPFIDEKKMP
Sorting sequences	Plant cell vacuole	+0+ + 0 -HSRFNPIRLPT
	Yeast vacuole	+ -LQRP-
	Animal cell lysosome	Mannose-6-phosphate "tag"

Note: Sequences are written in the single letter code. Charged residues are indicated + or –, and amino acids with hydroxyl groups on side chains (Thr or Ser residues) are indicated 0. ^ marks the position of endopeptidase cleavage.

Based on Austen, B. M. and Westwood, O. M. R., *Protein Targeting and Secretion*, Oxford University Press, Oxford, 1991. With permission from Oxford University Press.

tact organelles is feasible (e.g., chloroplasts, mitochondria), protein targeting can be studied via *in vitro* systems. In animals and yeast, systems for reconstituted *in vitro* protein transport between two organelles (e.g., the ER and Golgi complex) have also been developed.

Because the targeting signal is part of the protein itself, engineering of the respective gene involves modifications to the coding region only (Figure 3).[12] Two general approaches have commonly been undertaken:

1. A **"loss of function" approach** (Figure 3A) involves an analysis of the fate of mutants in which gene sequences (presumed to encode targeting signals of the corresponding protein) are deleted. The assumption here is that deletions in a targeting domain will cause the mutant protein to bypass the normal sorting reaction and, hence, result in its mislocalization in the transgenic host cells. If a targeting domain is implicated by these studies, it may be further delimited or defined by mutational analysis of specific residues. This "loss of function" approach has certain limitations because abolished targeting may be attributed to the deletion causing a nonspecific protein conformational change (affecting transport), rather than to the removal of a sequence involved in targeting per se. Hence, this approach is often combined with another one.
2. In the **"gain-of-function" approach** (Figure 3B), chimeric (fusion) genes are constructed, consisting of various lengths of coding sequence (from the gene coding the targeted protein) linked to an intact reporter gene coding sequence. This "gain-of-function" approach allows an identification of protein targeting domains that are sufficient to direct the reporter protein into the organelle under study. For example, Figure 3B shows this approach applied to identify the sorting signal of a vacuolar protein. One advantage of gene fusions is that the "reporter" or "passenger" protein may be easier to detect and localize in the heterologous host cells than the targeted protein itself; ideally, the added sequences present in the chimeric protein should not affect (i.e., reduce) reporter protein detection (e.g., enzymatic activity).[13] Cytosolic proteins are often preferred as reporters because they should not contain targeting signals; however, a prudent choice of a reporter protein is necessary because they may be unable to cross certain membranes.[14] This approach has been very useful for identifying discrete targeting signals on proteins, that is, those consisting of a specific stretch of contiguous amino acids. However, it is of limited use for the delineation of topogenic sequences referred to as "signal patches" (see earlier), those made up of noncontiguous regions of the polypeptide chain (Figure 2).

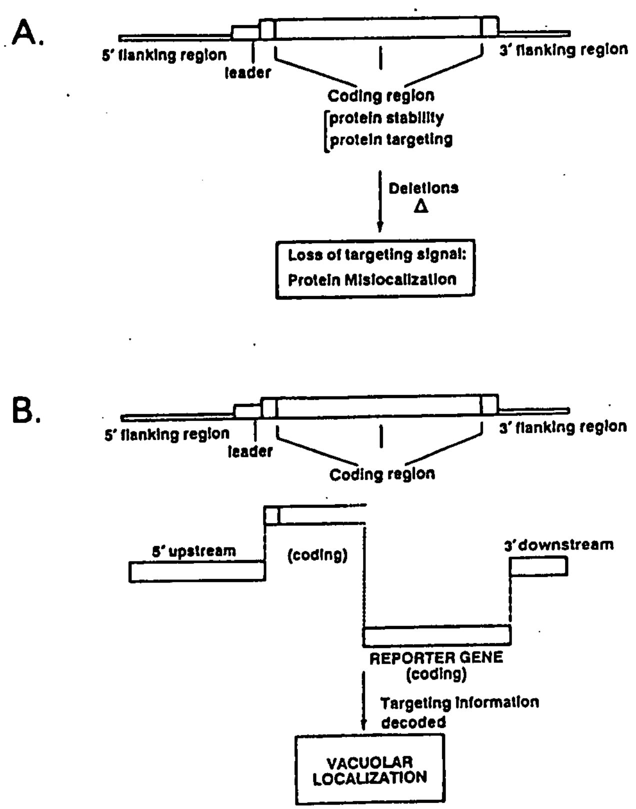

FIGURE 3. Approaches to study protein targeting. (A) "Loss of function" approach. Deletions in a targeting domain result in mislocalization of the mutant protein in the heterologous host cells. (B) "Gain of function" approach. The figure shows the approach applied to identify the amino acid sequences (or protein domain) sufficient to direct a reporter protein to the target organelle (e.g., the vacuole). Refer to text for further explanation. (From Kermode, A. R., in *Mechanisms of Plant Growth and Improved Productivity: Modern Approaches*, Basra, A. S., Ed., Marcel Dekker, New York, 1994, 317. With permission from Marcel Dekker.)

Specific methods have also been developed to identify the receptors involved in the recognition and decoding of specific sorting signals, as well as other components of the transport and targeting machinery; these are discussed in subsequent sections.

V. THE BIOSYNTHETIC TRANSPORT PATHWAY

As mentioned previously, some proteins synthesized in the cytosol (e.g., those subsequently routed to the vacuole, or destined for secretion from the cell) are transported along the biosynthetic transport pathway[15,16] or "secretory" pathway (reviewed in References 4 and 17). The organelles of this pathway include the ER (rough and smooth), Golgi apparatus, TGN, endosomes (where the exocytic and endocytic pathways converge), a variety of transport vesicles, vacuoles, the tonoplast, and the plasma membrane. As in other eukaryotic cells, the protein composition of these organelles in plant cells is highly dependent on the tissue or developmental stage of the cell (i.e., strict temporal and spatial regulation of gene expression is operative); it may also be influenced by external environmental signals. For example, vacuoles are acidic compartments that perform a variety of functions dependent upon the physiological status of the plant cell. Within the reserve tissues of many seeds, they perform a dual function — that is, as temporary storage depots (during seed development, when large amounts of storage proteins and other specialized proteins are synthesized and accumulated), and as sites of macromolecular hydrolysis, during the postgerminative phase of the plant lifecycle, when seedling growth must be supported. It is during this latter phase that the vacuole accumulates several hydrolytic enzymes involved in reserve mobilization, and the plant cell vacuole is thought of as equivalent to the animal lysosome. In contrast to the numerous small storage vacuoles found in the reserve tissues of seeds, developing cells of vegetative tissues (e.g., mesophyll cells of leaves) typically have one (or more) very prominent vacuole occupying much of the cell's volume. These vacuoles, like others, are multifunctional; in addi-

tion to providing a driving force for cell growth by maintaining turgor, they also have an important lytic role.[18]

Many vegetative reserve tissues (e.g., tubers, roots, bark) accumulate storage proteins and lectins in their vacuoles (often in a seasonal-dependent manner);[19–23] other vegetative tissues accumulate vacuolar storage proteins only when subjected to various stresses (e.g., nitrogen stress).[24] Pathogen invasion induces the synthesis of a variety of enzymes (including β-glucanases and chitinases) that are subsequently directed to both vacuolar and extracellular locations.[25,26]

Other major plant cell proteins transported along the "secretory" pathway are those destined for the tonoplast (the vacuolar membrane), the plasma membrane, and extracellular matrix (cell wall). Proteins transported to the plasma membrane include those that are essential for cellulose synthesis, hormone perception, and ion transport as well as those that mediate interactions with the cell wall and/or cytoskeleton.[27] Included in the most abundant proteins transported to the cell wall are the principal structural cell wall proteins, the hydroxyproline-rich glycoproteins (HRGPs) (e.g., the extensins), and the glycine- and proline-rich proteins, as well as some arabinogalactan proteins (found in specialized mucilages and gums) and the solanaceous lectins.[27–30] Other less abundant cell wall proteins include the cysteine-rich thionins, 28- and 70-kDa water-regulated proteins, a histidine-tryptophan-rich protein, and several cell wall enzymes (peroxidases, phosphatases, invertases, proteases).[30,31] The cell wall also appears to be a highly dynamic compartment; the abundance of several of its composite proteins is sensitive to external cues (such as wounding and pathogen invasion), as well as being subject to the normal spatial/temporal controls (Table 2).[30,32–48]

Tissues in the cereal caryopsis (i.e., the aleurone layer and scutellum) have a glandular function (during postgerminative seedling growth), and secrete a large number of hydrolytic enzymes that play an important role in endosperm storage reserve mobilization. Aleurone layers isolated from mature cereal grains have provided an important system for studying protein transport and secretion; upon treatment with gibberellin (GA) (and in the presence of calcium), a large proportion of this tissue's protein synthetic capacity becomes devoted to the production of several extracellular enzymes, including α-amylase, β-glucanase, ribonuclease, xylosidase, and acid phosphatase, each of which is actively secreted.[29,49]

The membranes surrounding organelles of the secretory pathway also represent specialized compartments for the many reactions catalyzed by integral membrane proteins. Often overlooked is the fact that different plant cell types contain different proportions of various membranes (reviewed in Reference 50), and this has raised questions about the mechanisms controlling membrane growth and changes in membrane lipid content/composition requiring the movement of lipids between organelles (see later discussion).

A. Unique Features of the Plant ER and Its Relationship to the Golgi Complex

The plant ER is a complex network of cisternae and tubules containing a single internal space (ER lumen). It is a dynamic organelle changing in organization during differentiation or environmental stress. It typically represents a fairly large proportion of a plant cell's total membrane (e.g., 30%), being particularly prominent in cell types exhibiting a high ratio of protein secretion or protein transport to the vacuole (Figure 4). The plant ER, in contrast to that of other eukaryotic cells, has several unique functions. For example, in seeds of some plant species, the ER is a site of aggregation and accumulation of some classes of storage proteins. Other more specialized roles of the plant ER may include anchoring the cytoskeleton, communication between the exterior of the cell and the cytoplasm, and communication between contiguous cells of the plant body. The former two roles have been attributed to the cortical ER of plant cells (i.e., the endomembrane system located in the peripheral layer of cytoplasm adjacent to the plasma membrane) (reviewed in Reference 51). A functional dynamic endomembrane continuum also exists between contiguous plant cells.[52] Intercellular communication between plant cells occurs through plasmodesmata, tubular structures embedded in the plant cell wall in association with the plasma membrane and ER. The ER associated with these plasmodesmata forms a communication pathway permitting intercellular passage of lipids, fatty acids, and important signal transduction molecules (e.g., the lipid secondary message, diacylglycerol). It may also provide the basis for plant hormone signal transmission, viral propagation, and pathogenic responses.[52]

TABLE 2
Examples of Plant Proteins Transported Along the Secretory Pathway and Conditions Regulating Their Expression

Protein class	Conditions
Structural cell[a] wall proteins	
Extensins (dicot)	Wounding, fungal infection, viral infection, fungal elicitors, endogenous elicitors, ethylene, red light, heat shock, gravity, glutathione, cell culturing, development
GRPs (dicot)	Development, viral infection, salicylic acid, abscisic acid, drought stress, wounding
GRPs (monocot)	Development, water stress, abscisic acid, mercuric chloride, wounding
PRPs	Wounding, endogenous elicitors, fungal elicitor, ethylene, cell culturing, light, red light, development
PRPs (nodulins)	Development
AGPs	Development, wounding
Secreted enzymes[b]	
α-Amylase	Abscisic acid, gibberellic acid, calcium, water stress, desiccation/rehydration
Chitinases	Development, fungal elicitors, abiotic elicitors
Plasma membrane proteins[c]	
pp34 (defense-related)	Oligogalacturonide elicitors
Plasma membrane ATPase	Development, hormones
Tonoplast/vacuolar proteins[d]	
TIP (tonoplast intrinsic proteins)	Development, water stress/osmoregulation
Slow vacuolar ion channel (of tonoplast)	Abscisic acid, gibberellic acid, calcium
Seed storage proteins (e.g., napin)	Development, abscisic acid, jasmonic acid, sugars, desiccation/rehydration
Vegetative storage proteins	Development (temporal), water deficit, wounding, nitrogen supply, jasmonic acid

The use of vital dyes has revealed some features of the internal organization of the ER. For example, the fluorochrome 3,3-dihexyloxacarbocyanine iodide stain shows that the ER of onion bulb epidermal cells is subdivided into three domains: cisternae (putative rough ER) and two forms of smooth ER, a peripheral tubular network and long tubular strands.[53]

The Golgi complex of plant cells (unlike that of most other eukaryotic cells) is actively engaged in the biosynthesis of the polysaccharide components of the cell wall (e.g., pectins and hemicelluloses), and many plant cells secrete far more polysaccharide than glycoprotein. In different cell types there may be distinct variations in the structural relations between the ER and Golgi stacks, perhaps dependent upon the nature of the secretory product. Not surprisingly, a closer association of the Golgi complex with the ER occurs in cell types exhibiting a higher rate of protein secretion than in plant cells engaged primarily in the secretion of carbohydrate-based molecules, in which only remote relations are observed (reviewed in Reference 3).

B. Signal-Dependent and Signal-Independent Steps Along the Secretory Pathway

1. Evidence for a Default Pathway

Proteins destined for transport along the secretory pathway are synthesized on ribosomes as-

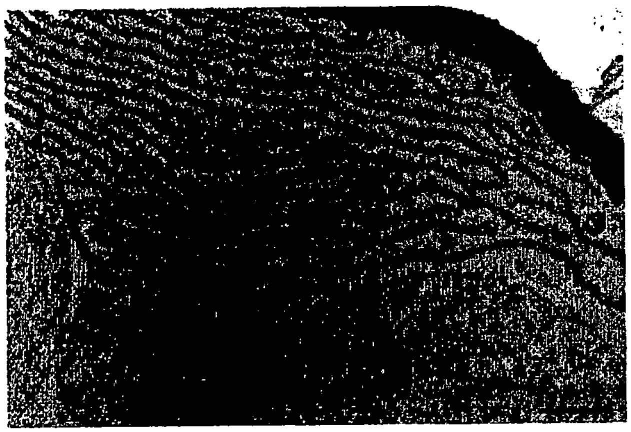

FIGURE 4. Plant endoplasmic reticulum (ER). Proliferation of the ER in a plant cell specialized for the accumulation of high amounts of protein in vacuoles. The electron micrograph shows a portion of a cell of developing common bean cotyledons. The cotyledons are synthesizing large amounts of storage protein that is cotranslationally translocated into the ER lumen for transport along the secretory pathway to protein storage vacuoles. The dark-stained area is the cell wall. Portions of protein storage vacuoles are visible at the bottom and left. Bar = 1 μm.(From Vitale, A., Ceriotti, A., and Denecke, J., *J. Exp. Bot.*, 44, 1417, 1993. With permission from Oxford University Press. Courtesy of Franco Faoro.)

sociated with the ER. The first step of entry into the pathway is mediated by a N-terminal signal peptide on the nascent protein that directs a transmembrane translocation from the cytosol to the lumen of the ER,[54] a step generally accompanied by signal peptide cleavage (see later discussion). The ER contains a mixture of proteins with multiple destinations. Some proteins will become permanent residents of the ER; others are exported to the Golgi apparatus for retention there, or for subsequent distribution to the cell surface or lysosome/vacuole. How this complex traffic pattern is organized, and what steps along the pathway occur by default (i.e., are signal-independent), or alternatively, require specific targeting signals, have been subjects for both speculation and debate (reviewed in References 16 and 55 through 60). For example, there have been arguments for proteins requiring specific signals for export out of the ER; others have argued for nonselective export out of the ER, with positive signals being required for ER retention. The available evidence from eukaryotic systems (including plants) indicates that each of the steps along the intracellular route leading to constitutive secretion from the cell (i.e., ER to Golgi complex, movement through the Golgi stacks, and movement from the Golgi complex to the cell surface) occurs by default: secreted and plasma membrane proteins are carried along by a nonselective "bulk-flow" process.[16,17,59,61] Proteins destined for targets other than the cell surface must contain additional positive topogenic information. Thus, additional information is required for selective retention in the ER (or the Golgi complex), or for diversion of proteins away from the bulk-flow pathway to one of the branch pathways within the TGN (e.g., to the animal lysosome or plant/yeast vacuole) (Figure 5).

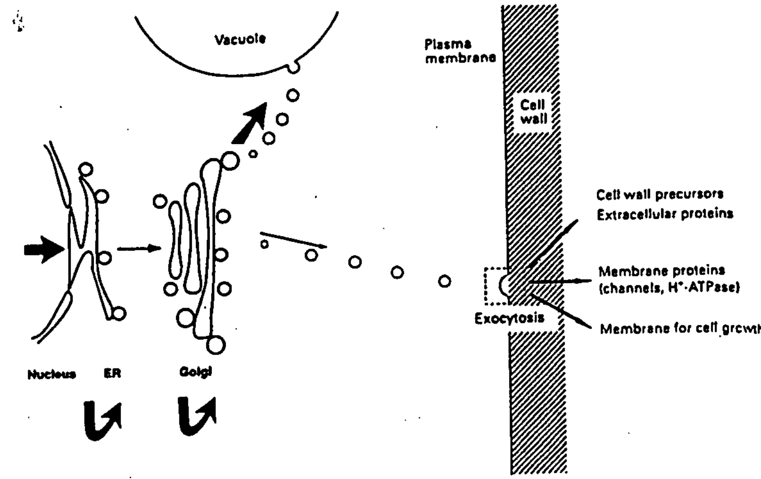

FIGURE 5. Current model of protein transport through the plant secretory pathway. Thin arrows depict signal-independent transport and represent bulk-flow (the "default" pathway). Thick arrows denote transport steps that are signal-mediated, including translocation across the ER membrane, retention of resident proteins in the ER and Golgi complex, and transport to vacuoles.

There are several arguments in favor of a bulk-flow model in which (constitutive) secretion is the default fate for a soluble protein containing no additional specific targeting information (over that of the signal peptide).[17,29,62–65] Perhaps the most striking evidence for the existence of a default pathway in animal cells comes from the work of Wieland et al.,[66] who devised a bulk phase marker of the secretory pathway. A synthetic tripeptide consisting of the glycosylation sequence Asn-Tyr-Thr, esterified to make it membrane permeable, can enter cells, reach the ER lumen where it becomes glycosylated (thus rendering it membrane impermeant), and then be rapidly secreted, predominantly along the normal pathway (i.e., via the Golgi complex). It is assumed that the tripeptide contains no transport or retention signals and defines the bulk-flow rate of ER to cell surface movement and thereby the default pathway.[57,61] Moreover, the bulk-flow rate defined by this marker is sufficiently rapid to account for the export of most secretory or membrane proteins, being close to the rate of transport of the most rapidly secreted proteins.[66] Although there are some valid criticisms regarding the appropriateness of the glycosylated tripeptide as a bulk phase marker,[55,58,59] there is currently no compelling reason to postulate the existence of a positive ER export signal for any protein.[59]

The loss or disruption of a defined positive sorting signal on a protein (e.g., by mutation or deletion) generally leads to its transport along the default pathway (i.e., missorting and secretion). Similarly, when signal-dependent sorting to the animal lysosome or to specialized secretory vesicles (involved in regulated secretion) is saturated or incapacitated, the bulk-flow pathway to the cell surface seems to be the route taken by default. In I-cells that are unable to tag lysosomal hydrolases with the required sorting signals (i.e., mannose-6-phosphate residues) and in cells deficient in one of the mannose-6-phosphate receptors (see later discussion), a large fraction of lysosomal hydrolases are constitutively secreted.[67,68]

Significant mistargeting and secretion also occurs in yeast cells when two proteins (normally targeted to the vacuole) are overexpressed, presumably because the capacity of vacuolar sorting machinery is surpassed.[69,70] Removal of putative ER-retention signals from ER-resident proteins causes them to be transported along the secretory pathway, even though they would not do so normally, and hence, are not expected to have an export/transport signal.[70–72] Conversely, mutations in secreted or plasma membrane proteins that abolish transport and lead to their retention have subsequently been shown to affect transport out of the ER by indirect means (reviewed in References 60, 73, and 74). Deletion or disruption of a specific export signal is not operative here; rather, these proteins are unable to undergo the normal folding/assembly processes required for subsequent transport out of the ER (see later discussion).

Disruption of signal-dependent sorting in the TGN by chemical treatments that affect the pH of the transport pathway (and presumably receptor-ligand interactions such as chloroquine and monensin) also cause mistargeting and secretion.[67,75–77] Mistargeting and transport of proteins along the bulk-flow pathway occur when animal cells are treated with the sodium ionophore monensin, which raises the pH of the TGN.[77] A similar phenomenon occurs in plant cells; treatment of pea and jackbean cotyledons results in the transport of storage proteins and lectins (normally accumulated in the storage vacuole/protein body) to the plasma membrane and cell wall.[78,79]

Likewise, in roots of transgenic tomato plants, proteinase inhibitors I and II (primarily vacuolar in location) are found in greater abundance at the cell wall following monensin treatment.[80] Not all vacuolar storage proteins behave in this manner; pro-barley lectin and bean phytohemagglutinin (PHA) are retained intracellularly following treatment with monensin.[81,82] The varying effects of this ionophore on the trafficking of secretory products may reflect structural and functional cell type-specific differences in the organization of plant Golgi stacks.[83]

Secretion is the outcome in plant cells when a protein contains no additional targeting information over that of the signal peptide.[62–65] In studies of chimeric proteins expressed in transgenic tobacco, a signal peptide (e.g., from the vacuolar proteins PHA and patatin) is sufficient to direct a cytosolic reporter protein (e.g., pea albumin 2 and β-glucuronidase, or GUS) into the ER and leads to transport along the secretory pathway via a default/bulk-flow mechanism. Likewise, in tobacco cells transformed by electroporation, bacterial cytosolic enzymes, utilized as reporters, enter the secretory pathway (when linked to the signal peptide of an extracellular pathogenesis-related protein, PR1, or that of the cell wall glycoprotein, extensin) and are secreted.[64,84] Secretion in these transformed tobacco cells is relatively inefficient; however, the results are indicative that secretion can occur independently of active sorting by non-specific migration through the secretory pathway.

2. Signal-Dependent Steps Along the Secretory Pathway

In contrast to the signal-independent export of proteins out of the ER (and intra-Golgi transport by bulk flow), specific signals for retention have been described for some ER and Golgi proteins (Figure 5, Table 1). Perhaps the best defined retention signal is the tetrapeptide His/Lys-Asp-Glu-Leu (HDEL or KDEL), which is present at the C-terminus of several soluble resident ER proteins, in animals, yeast, and plants (see later discussion).

Sorting information is required to divert proteins from bulk-flow transport to the yeast cell vacuole (via sorting in the TGN); recent evidence suggests a similar requirement for transport of proteins to the plant cell vacuole. As mentioned earlier, a chimeric gene consisting of the signal sequence of the vacuolar seed protein PHA and the coding sequence of a cytosolic seed protein (pea albumin 2) has been expressed in seeds and suspension cultured cells of transgenic tobacco.[62,63] The signal peptide is necessary and sufficient to direct entry of the chimeric protein into the secretory pathway; however, it does not accumulate in the vacuole (e.g., in seeds) and is efficiently secreted from suspension cultured cells.

In animal cells, proteins *en route* to the lysosome share a common pathway of intracellular

transport with plasma membrane and constitutively secreted proteins that extends as far as the TGN (reviewed in Reference 85). However, the fate of soluble lysosomal proteins (e.g., lysosomal hydrolases) that are all glycosylated in the ER, is determined earlier in the Golgi stack. After arrival in the *cis*-Golgi, a series of modifications by specific Golgi enzymes (*N*-acetylglucosamine phosphotransferase and phosphoglycosidase) ultimately result in a mannose-6-phosphate tag on soluble lysosomal proteins. The specificity of the reaction lies with the enzyme *N*-acetylglucosamine phosphotransferase, which recognizes a conformation-dependent signal patch on lysosomal hydrolases, such that only proteins destined to reside in lysosomes are appropriately modified (reviewed in Reference 6). Later in the pathway, the mannose-6-phosphate tag allows the proteins to bind to mannose-6-phosphate receptors and hence be specifically sorted for delivery to the lysosome in the TGN. Release of lysosomal proteins from their receptors occurs in an acidified (pre-lysosomal, endosomal) compartment; subsequently, the receptors recycle back to the Golgi (or to the cell surface because these receptors are also involved in endocytosis) while the proteins are packaged into lysosomes.

In animal cells, there are two distinct pathways of secretion viz., constitutive and regulated.[16,56,86,87] In specialized cells involved in regulated secretion (that are also capable of secreting proteins constitutively), the regulated secretory products are concentrated and stored in dense vesicles (granules) in the cytosol. Fusion of these vesicles with the cell surface occurs only after receipt of a specific extracellular signal (e.g., a hormone or neurotransmitter, depending on the cell type). This process, termed exocytosis,[88] is thus regulated, and gives rise to the controlled secretion of the selected contents of the secretory storage vesicle.[56,57] By contrast, secretion via bulk flow to the cell surface is constitutive and continuous. Characterization of the signals that permit membership or entry of specific proteins into storage vesicles is not yet complete; however, it is clear that their content is highly selected. A form of selective precipitation in the TGN may be involved; "carrier-type" proteins have been implicated in the mechanism.[89]

In plants, the constitutive pathway of protein secretion is the principal pathway along which proteins are secreted to the cell exterior;[17,29] in general, there is a close temporal correlation between the synthesis of proteins and their secretion from the cell (e.g., cereal α-amylase).[90,91]

Regulated secretion occurs in the green alga *Clamydomonas reinhardii*. Here the release of stored lysin (a cell-wall-degrading enzyme) is induced by gamete sexual signaling.[92]

As pointed out by Satiat-Jeunemaitre and Hawes,[3] the terms 'regulated' and 'constitutive' are somewhat misleading; constitutive secretion is regulated in the sense that it is influenced by a number of external factors such as hormones and environmental stresses (see later discussion).

a. Signal-Dependent Translocation Across the ER Membrane

Translocation across the membrane of the rough ER represents the first signal-dependent step along the secretory pathway. Proteins destined for this step contain a hydrophobic signal peptide (Figure 1, Table 1) that serves as a requisite signal to target the ribosome to the rough ER. The development of *in vitro* protein translation-translocation systems has been important for the characterization of some of the molecular components that regulate ER targeting/translocation in eukaryotes (reviewed in References 10 and 93). Cell-free translation systems have been prepared from lysates of wheat-germ, reticulocytes, and yeast. They contain the ribosomes and additional co-factors required for protein biosynthesis, but need to be supplemented with an energy source; typically, a source of exogenous amino acids, including a radiolabelled amino acid such as [^{35}S]-methionine is added along with mRNAs. Reaction mixtures can be supplemented with vesiculated portions of the ER (microsomes) that are isolated by homogenizing cells in isotonic buffers, then purified from other membrane components by centrifugation on sucrose density gradients (Figure 6).[94] In this way, the nascent polypeptide chain is targeted and inserted into the lumen of the microsomes where

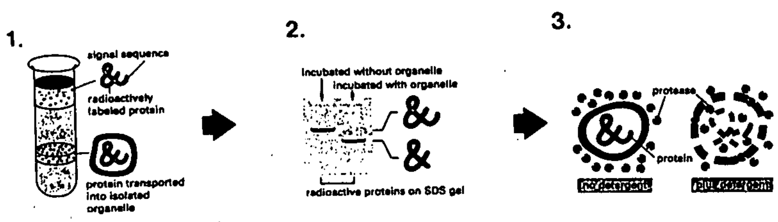

FIGURE 6. Biochemical approaches for studying the mechanism of protein translocation. In this approach a labeled protein containing a specific signal sequence is transported into isolated organelles *in vitro*. The labeled protein is usually produced by cell-free translation of a purified mRNA encoding the protein; radioactive amino acids are used to label the newly synthesized protein so that it can be distinguished from the many other proteins that are present in the *in vitro* translation system. Three methods are commonly used to test if the labeled protein has been translocated into the organelle: (1) The labeled protein co-fractionates with the organelle during centrifugation; (2) The signal sequence is removed by a specific protease that is present inside the organelle; and (3) The protein is protected from digestion when proteases are added to the incubation medium, but is susceptible if a detergent is first added to disrupt the organelle membrane. By exploiting such *in vitro* assays, one can determine what components (proteins, ATP, GTP, etc.) are required for the translocation process. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 3rd ed., Garland Publishing, New York, 1994. With permission from Garland Publishing.)

the signal peptide is cleaved off, producing a decrease in the molecular mass of the protein. The products of translation and the effects of translocation can be viewed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography following an immunopurification step (Figure 6). Translocation is demonstrated by the addition of proteases; proteins within the microsomes are protected from digestion unless solubilized with detergent.

Experiments to establish the autonomous nature of signal peptides and their role in ER targeting/translocation typically involve the generation of a chimeric gene construct (to encode a chimeric mRNA and resultant protein), in which DNA encoding a signal peptide is linked to that encoding a passenger (e.g., cytosolic) protein. This chimeric sequence can then be ligated into a plasmid downstream of an active promoter that is recognized by SP6 RNA polymerase (Figure 7). When the resultant mRNA produced by this *in vitro* transcription system is translated in the cell-free system supplemented with microsomes, the protein is translocated across the microsome (ER) membrane as confirmed by protease treatment (Figures 6 and 7).

In vitro protein import systems (as well as subcellular localization of chimeric proteins synthesized in stably transformed tobacco; see earlier) have established that the signal peptides of plant proteins generally function with a high degree of autonomy, being both necessary and sufficient to direct passenger proteins into the lumen of the ER. An examination of the derived amino acid sequences of plant secretory and vacuolar proteins shows that all of them have a N-terminal domain with the properties of other eukaryotic signal sequences.[17,95–97] Despite great sequence diversity between eukaryotic signal peptides, most have similar overall features viz., a charged N-terminal region, a core of 10 to 15 hydrophobic amino acids, and a more polar C-terminal sequence (Figure 8).[98] Translocation is mediated by receptor-like systems[54,99,100] (termed the translocon) that involve proteins in the cytosol and on the target membrane; this complex cellular machinery is able to recognize signal peptides, despite their variation in amino acid sequence. Studies on the well-characterized mammalian ER have identified several distinct components of such a receptor-like system; these act sequentially and, hence, greatly enhance the specificity of the sys-

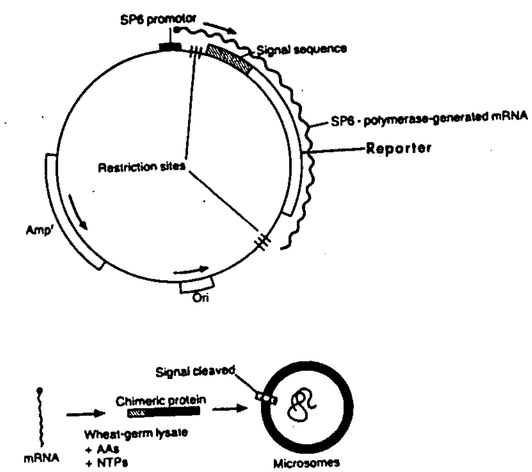

FIGURE 7. Generation of a chimeric protein. DNA encoding a signal sequence ligated to DNA encoding a normally cytoplasmic protein is transcribed and translated to yield a precursor protein that is translocated into microsomal vesicles. The signal sequence is cleaved off on translocation. (From Austen, B. M. and Westwood, O. M. R., *Protein Targeting and Secretion*, Oxford University Press, Oxford, 1991. FIGURE 8. Structure and hydropathy index of the signal peptide of the plant protein, tomato fruit polygalacturonase. The sequence was deduced from the nucleotide sequence of the cDNA and the signal sequence cleavage site by radiosequencing of the product of *in vitro* translation and *in vitro* processing (see Bennett and Osteryoung, 1991 and references therein). The n-region is characterized by a single positively charged amino acid (+), the h-region by a core of hydrophobic amino acids (^), and the c-region by small neutral amino acids (*) at positions -1 and -3. (From Bennett, A.B., and Osteryoung, K.W., in Plant Genetic Engineering, Grierson, D., Ed., Chapman and Hall, New York, 1991, 199. With permission from Chapman and Hall.)

tem (reviewed in References 5, 15, 93, 101 and 102). One component is the signal recognition particle (SRP), a ribonucleoprotein complex consisting of a molecule of RNA and six polypeptide chains, including a 54-kDa protein with a guanosine trisphosphate (GTP)-binding domain. The 54-kDa polypeptide subunit (SRP-54) selectively binds to the signal peptide sequence on the precursor as it emerges from the ribosome, temporarily halting translation. The ternary complex (consisting of the ribosome, nascent precursor, and SRP) is targeted to the rough ER membrane due to the affinity of the SRP for a 72-kDa integral ER protein (part of the SRP receptor or docking protein). Contact between the SRP and its receptor results in the dissociation of SRP from both the ribosome and the signal sequence. The ribosome becomes membrane bound (possibly by associating with several ER proteins), translation resumes, and the signal sequence is inserted into the translocation site to begin the translocation event. Subsequently, the SRP is released from its receptor (by hydrolysis of a bound GTP molecule), and the SRP is free to enter a new targeting cycle (Figure 9). At least two steps of the translocation event appear to be controlled by the hydrolysis of GTP, again contributing to the specificity of the system.[101] The GTPase cycle of SRP-54 may control signal sequence insertion into the translocation channel.[102] The ER-translocation process in plants is similar to that in animals and fungi. The existence of the SRP and SRP receptor in plants has now been documented. Moreover, efficient synthesis, translocation, and processing of plant secretory proteins occur in animal and fungal heterologous systems; thus, strong evidence exists for a common mechanism of protein translocation in eukaryotes.[91,103,104] The 54-kDa protein subunit of the SRP of *Arabidopsis* is encoded by at least two genes and exhibits a high degree of sequence similarity to the SRP-54 polypeptides of mammals and yeast.[105] The functional domains characteristic of the yeast and mammalian proteins are also present, viz., a N-terminal GTP-binding (G-) domain and a C-terminal methionine-rich (M-) domain, capable of forming amphiphilic α-helices (see below).

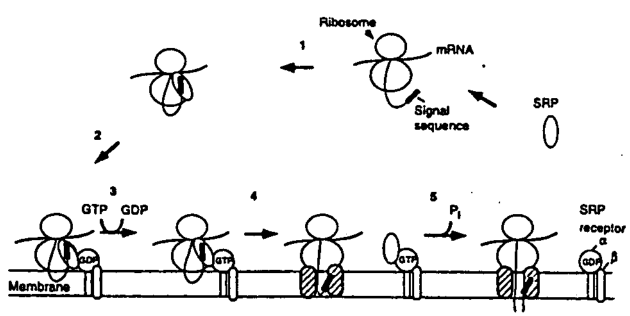

FIGURE 9. The ER targeting cycle. The scheme shows the first steps in protein translocation across the ER membrane. When the signal sequence of a growing polypeptide chain has emerged from the ribosome, it is recognized and bound by the SRP (step 1). In step 2, the complex containing the ribosome, nascent chain, and SRP binds to the ER membrane through an interaction of the SRP with its membrane receptor, which consists of two subunits. In step 3, GDP is exchanged for GTP at the SRP receptor. In step 4, the SRP is released from the ribosome and from the signal sequence. The ribosome becomes membrane-bound, probably by its interaction with SEC61 or associated proteins, and translocation begins. In step 5, the SRP is released from its receptor by GTP hydrolysis and can then enter a new targeting cycle. Whether the two subunits of the SRP receptor dissociate during the SRP cycle is not known. (From Rapoport, T. A., *Science*, 258, 931, 1992. With permission from T. A. Rapoport.)

Solutions to the enigma of how diverse signal peptide sequences/shapes can be recognized by, and accommodated within, the 54-kDa polypeptide component of the SRP have been sought (reviewed in Reference 101). Sequestration of signal peptide sequences may occur in a hydrophobic methionine-rich pocket formed by secondary structural domains (amphipathic α-helices) of the 54-kDa SRP protein (the M-domain). More specifically, the unbranched methionine side chains lining this pocket provide projecting flexible "bristles" that recognize and accommodate only the common hydrophobic core of signal peptides, albeit diverse in primary sequence.[93,101,102,106] Less is known about the mechanics of protein translocation; transport through a proteinaceous pore (rather than movement directly through the lipid bilayer) is suggested by studies in yeast and mammals.[107,108] Electrophysiological techniques indicate protein conducting channels of discrete size in rough ER-derived vesicles.[109] Likewise, analyses using proteins tagged with fluorescent amino acid analogs indicate that the nascent polypeptide resides in an aqueous environment following its insertion into the translocation site.[110] A tight seal between the ribosome and the translocation site restricts solute flow across the membrane; both these properties are consistent with a hydrophilic, proteinaceous translocation site. The growing number of putative translocon components identified in various eukaryotic organisms (Table 3) attests to the complexity of the translocation machinery. Some of these components are directly involved in the translocation process per se; others likely participate in chemical modifications of a nascent polypeptide or in its folding and assembly. In yeast, identification of proteins comprising the central core of the translocon came from genetic selection to obtain yeast mutants defective in translocation and causing the cytoplasmic accumulation of precursors for secretory proteins *in vivo* and *in vitro*. In this way, SEC61, SEC62, and SEC63 were identified as integral membrane proteins assembled together with two additional polypeptides into a multisubunit complex in the ER.[111,112] Crosslinking studies (see below) indicate a direct role in translocation for SEC61; this protein is cross-linked to polypeptides trapped in translocation.[113] Mutations in *sec62* and *sec63* genes decrease the ability of the SEC61 protein to interact with translocating polypeptides, and a role during the early stages of the translocation process has been proposed. Another protein called the binding protein (BiP) (a luminal ER protein; see later discussion) is thought by some to play a facilitory role in the translocation of precursors in yeast. More specifically, protein entry into the ER lumen may be facilitated by cycles of BiP binding and adenosine triphosphate (ATP) hydrolysis-dependent dissociation.[102] The protein may be relatively more important for the posttranslational mode of translocation (e.g., in yeast), determining the directionality of transport by binding to the incoming protein and preventing the inappropriate release/exit of proteins from the cytoplasmic face of the translocation channel. A role in the folding of translocation components

TABLE 3
Possible Components of the Translocation Site of the ER Membrane[a]

Protein	Occurrence	Function
SEC61/Y	Yeast, bacteria, mammals, fish	Constituent of a protein-conducting channel
TRAM protein	Mammals	Early function in translocation
SEC62-SEC63 complex	Yeast	Early function in translocation
SSR complex	Mammals, fish, birds	Unknown
Signal peptidase complex	Yeast, mammals	Signal peptide cleavage
Oligosaccharyl transferase	Mammals, yeast	Asn-glycosylation
mp30	Mammals	Unknown

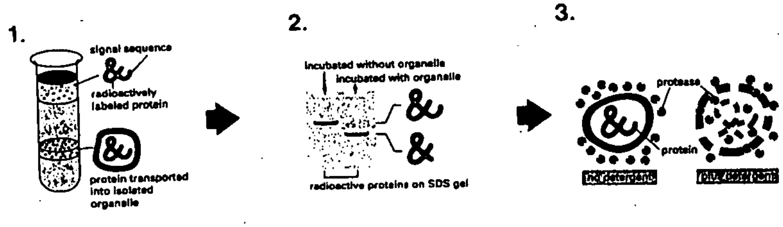

FIGURE 6. Biochemical approaches for studying the mechanism of protein translocation. In this approach a labeled protein containing a specific signal sequence is transported into isolated organelles *in vitro*. The labeled protein is usually produced by cell-free translation of a purified mRNA encoding the protein; radioactive amino acids are used to label the newly synthesized protein so that it can be distinguished from the many other proteins that are present in the *in vitro* translation system. Three methods are commonly used to test if the labeled protein has been translocated into the organelle: (1) The labeled protein co-fractionates with the organelle during centrifugation; (2) The signal sequence is removed by a specific protease that is present inside the organelle; and (3) The protein is protected from digestion when proteases are added to the incubation medium, but is susceptible if a detergent is first added to disrupt the organelle membrane. By exploiting such *in vitro* assays, one can determine what components (proteins, ATP, GTP, etc.) are required for the translocation process. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 3rd ed., Garland Publishing, New York, 1994. With permission from Garland Publishing.)

the signal peptide is cleaved off, producing a decrease in the molecular mass of the protein. The products of translation and the effects of translocation can be viewed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and autoradiography following an immunopurification step (Figure 6). Translocation is demonstrated by the addition of proteases; proteins within the microsomes are protected from digestion unless solubilized with detergent.

Experiments to establish the autonomous nature of signal peptides and their role in ER targeting/translocation typically involve the generation of a chimeric gene construct (to encode a chimeric mRNA and resultant protein), in which DNA encoding a signal peptide is linked to that encoding a passenger (e.g., cytosolic) protein. This chimeric sequence can then be ligated into a plasmid downstream of an active promoter that is recognized by SP6 RNA polymerase (Figure 7). When the resultant mRNA produced by this *in vitro* transcription system is translated in the cell-free system supplemented with microsomes, the protein is translocated across the microsome (ER) membrane as confirmed by protease treatment (Figures 6 and 7).

In vitro protein import systems (as well as subcellular localization of chimeric proteins synthesized in stably transformed tobacco; see earlier) have established that the signal peptides of plant proteins generally function with a high degree of autonomy, being both necessary and sufficient to direct passenger proteins into the lumen of the ER. An examination of the derived amino acid sequences of plant secretory and vacuolar proteins shows that all of them have a N-terminal domain with the properties of other eukaryotic signal sequences.[17,95–97] Despite great sequence diversity between eukaryotic signal peptides, most have similar overall features viz., a charged N-terminal region, a core of 10 to 15 hydrophobic amino acids, and a more polar C-terminal sequence (Figure 8).[98] Translocation is mediated by receptor-like systems[54,99,100] (termed the translocon) that involve proteins in the cytosol and on the target membrane; this complex cellular machinery is able to recognize signal peptides, despite their variation in amino acid sequence. Studies on the well-characterized mammalian ER have identified several distinct components of such a receptor-like system; these act sequentially and, hence, greatly enhance the specificity of the sys-

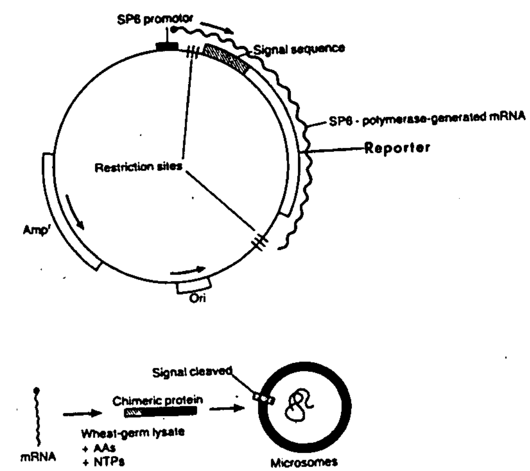

FIGURE 7. Generation of a chimeric protein. DNA encoding a signal sequence ligated to DNA encoding a normally cytoplasmic protein is transcribed and translated to yield a precursor protein that is translocated into microsomal vesicles. The signal sequence is cleaved off on translocation. (From Austen, B. M. and Westwood, O. M. R., *Protein Targeting and Secretion*, Oxford University Press, Oxford, 1991. FIGURE 8. Structure and hydropathy index of the signal peptide of the plant protein, tomato fruit polygalacturonase. The sequence was deduced from the nucleotide sequence of the cDNA and the signal sequence cleavage site by radiosequencing of the product of *in vitro* translation and *in vitro* processing (see Bennett and Osteryoung, 1991 and references therein). The n-region is characterized by a single positively charged amino acid (+), the h-region by a core of hydrophobic amino acids (^), and the c-region by small neutral amino acids (*) at positions -1 and -3. (From Bennett, A.B., and Osteryoung, K.W., in Plant Genetic Engineering, Grierson, D., Ed., Chapman and Hall, New York, 1991, 199. With permission from Chapman and Hall.)

tem (reviewed in References 5, 15, 93, 101 and 102). One component is the signal recognition particle (SRP), a ribonucleoprotein complex consisting of a molecule of RNA and six polypeptide chains, including a 54-kDa protein with a guanosine trisphosphate (GTP)-binding domain. The 54-kDa polypeptide subunit (SRP-54) selectively binds to the signal peptide sequence on the precursor as it emerges from the ribosome, temporarily halting translation. The ternary complex (consisting of the ribosome, nascent precursor, and SRP) is targeted to the rough ER membrane due to the affinity of the SRP for a 72-kDa integral ER protein (part of the SRP receptor or docking protein). Contact between the SRP and its receptor results in the dissociation of SRP from both the ribosome and the signal sequence. The ribosome becomes membrane bound (possibly by associating with several ER proteins), translation resumes, and the signal sequence is inserted into the translocation site to begin the translocation event. Subsequently, the SRP is released from its receptor (by hydrolysis of a bound GTP molecule), and the SRP is free to enter a new targeting cycle (Figure 9). At least two steps of the translocation event appear to be controlled by the hydrolysis of GTP, again contributing to the specificity of the system.[101] The GTPase cycle of SRP-54 may control signal sequence insertion into the translocation channel.[102] The ER-translocation process in plants is similar to that in animals and fungi. The existence of the SRP and SRP receptor in plants has now been documented. Moreover, efficient synthesis, translocation, and processing of plant secretory proteins occur in animal and fungal heterologous systems; thus, strong evidence exists for a common mechanism of protein translocation in eukaryotes.[91,103,104] The 54-kDa protein subunit of the SRP of *Arabidopsis* is encoded by at least two genes and exhibits a high degree of sequence similarity to the SRP-54 polypeptides of mammals and yeast.[105] The functional domains characteristic of the yeast and mammalian proteins are also present, viz., a

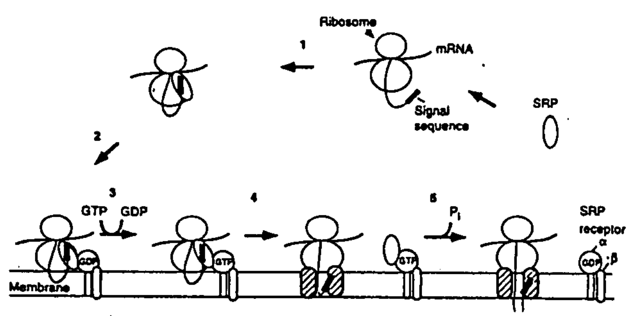

FIGURE 9. The ER targeting cycle. The scheme shows the first steps in protein translocation across the ER membrane. When the signal sequence of a growing polypeptide chain has emerged from the ribosome, it is recognized and bound by the SRP (step 1). In step 2, the complex containing the ribosome, nascent chain, and SRP binds to the ER membrane through an interaction of the SRP with its membrane receptor, which consists of two subunits. In step 3, GDP is exchanged for GTP at the SRP receptor. In step 4, the SRP is released from the ribosome and from the signal sequence. The ribosome becomes membrane-bound, probably by its interaction with SEC61 or associated proteins, and translocation begins. In step 5, the SRP is released from its receptor by GTP hydrolysis and can then enter a new targeting cycle. Whether the two subunits of the SRP receptor dissociate during the SRP cycle is not known. (From Rapoport, T. A., *Science*, 258, 931, 1992. With permission from T. A. Rapoport.)

N-terminal GTP-binding (G-) domain and a C-terminal methionine-rich (M-) domain, capable of forming amphiphilic α-helices (see below).

Solutions to the enigma of how diverse signal peptide sequences/shapes can be recognized by, and accommodated within, the 54-kDa polypeptide component of the SRP have been sought (reviewed in Reference 101). Sequestration of signal peptide sequences may occur in a hydrophobic methionine-rich pocket formed by secondary structural domains (amphipathic α-helices) of the 54-kDa SRP protein (the M-domain). More specifically, the unbranched methionine side chains lining this pocket provide projecting flexible "bristles" that recognize and accommodate only the common hydrophobic core of signal peptides, albeit diverse in primary sequence.[93,101,102,106] Less is known about the mechanics of protein translocation; transport through a proteinaceous pore (rather than movement directly through the lipid bilayer) is suggested by studies in yeast and mammals.[107,108] Electrophysiological techniques indicate protein conducting channels of discrete size in rough ER-derived vesicles.[109] Likewise, analyses using proteins tagged with fluorescent amino acid analogs indicate that the nascent polypeptide resides in an aqueous environment following its insertion into the translocation site.[110] A tight seal between the ribosome and the translocation site restricts solute flow across the membrane; both these properties are consistent with a hydrophilic, proteinaceous translocation site. The growing number of putative translocon components identified in various eukaryotic organisms (Table 3) attests to the complexity of the translocation machinery. Some of these components are directly involved in the translocation process per se; others likely participate in chemical modifications of a nascent polypeptide or in its folding and assembly. In yeast, identification of proteins comprising the central core of the translocon came from genetic selection to obtain yeast mutants defective in translocation and causing the cytoplasmic accumulation of precursors for secretory proteins *in vivo* and *in vitro*. In this way, SEC61, SEC62, and SEC63 were identified as integral membrane proteins assembled together with two additional polypeptides into a multisubunit complex in the ER.[111,112] Crosslinking studies (see below) indicate a direct role in translocation for SEC61; this protein is cross-linked to polypeptides trapped in translocation.[113] Mutations in *sec62* and *sec63* genes decrease the ability of the SEC61 protein to interact with translocating polypeptides, and a role during the early stages of the translocation process has been proposed. Another protein called the binding protein (BiP) (a luminal ER protein; see later discussion) is thought by some to play a facilitory role in the translocation of precursors in yeast. More specifically, protein entry into the ER lumen may be facilitated by cycles of BiP binding and adenosine triphosphate (ATP) hydrolysis-dependent dissociation.[102] The protein may be relatively more important for the posttranslational mode of translocation (e.g., in yeast), determining the directionality of transport by binding to the incoming protein and preventing the inappropriate release/exit of proteins from the cytoplasmic face of the translocation channel. A role in the folding of translocation components

TABLE 3
Possible Components of the Translocation Site of the ER Membrane[a]

Protein	Occurrence	Function
SEC61/Y	Yeast, bacteria, mammals, fish	Constituent of a protein-conducting channel
TRAM protein	Mammals	Early function in translocation
SEC62-SEC63 complex	Yeast	Early function in translocation
SSR complex	Mammals, fish, birds	Unknown
Signal peptidase complex	Yeast, mammals	Signal peptide cleavage
Oligosaccharyl transferase	Mammals, yeast	Asn-glycosylation
mp30	Mammals	Unknown

like the SEC62-SEC63 protein complex has also been suggested.[93]

Identification of potential components of the mammalian translocon has also been aided by the use of photochemicals or chemicals that cross-link nascent secretory proteins to adjacent integral ER membrane proteins. These studies implicated a 35- to 39-kDa glycoprotein (translocating chain-associated membrane [TRAM] protein) and a 34- to 37-kDa nonglycoprotein (homologous to yeast SEC61 and *Escherichia coli* SECY proteins).[114,115]

Reconstitution of detergent-solubilized rough ER proteins into translocation competent proteoliposomes allows the functional evaluation of putative translocation factors.[108,114] In mammalian cells, the SRP, the SRP receptor, SEC61, and the TRAM protein may participate directly in translocation because translocation is successful using these purified components. However, several additional stimulatory factors probably exist (perhaps mammalian homologs of the yeast proteins, SEC62, and SEC63). The TRAM protein may contact the N-terminal regions of nascent polypeptides at an early stage; a requirement for this protein depends upon the synthesized product. For example, it is essential for the transport of several precursors, but is only stimulatory for others. Further components assumed to be involved in the process include putative ribosome receptors of 34 kDa[116,117] and 180 kDa,[118] a membrane protein of 30 kDa with affinity for SRP (mp30),[119] and an unidentified ATP-binding membrane protein.[120] However, the function of these components, if any, is either disputed or not demonstrated yet (Figure 10) (see Reference 108 and references therein).

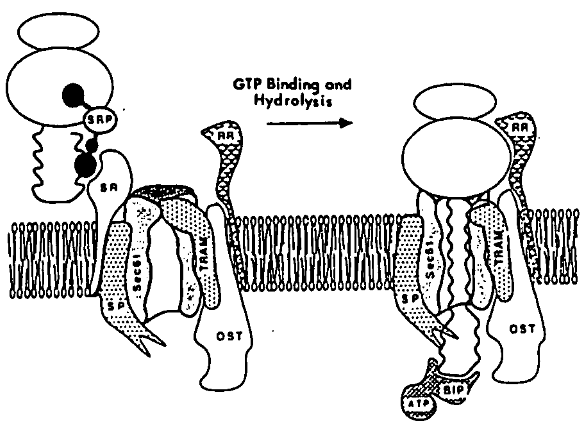

FIGURE 10. A schematic representation of the targeting and transport phases of a protein translocation reaction. The left portion of the diagram depicts SRP-dependent targeting of a ribosome to a preassembled translocation site comprised of the SRP receptor (SR), SEC61, TRAM, signal peptidase (SP), oligosaccharyltransferase (OST), and a ribosome receptor (RR). Conformational changes in Sec61p and TRAM that mediate channel gating are speculative. GTP binding and hydrolysis reactions permit SRP dissociation from the signal sequence and SRP receptor. Polypeptides traversing the channel contact TRAM and SEC61. Luminal reactions mediated by signal peptidase and oligosaccharyltransferase may inhibit reversible transport through the channel, whereas BiP may actively facilitate transport by binding the precursor as it emerges into the lumen. (From Gilmore, R., *Cell*, 75, 589, 1993. With permission from Cell Press.)

A hydrophilic protein is completely translocated across the rough ER if it is preceded by a signal that undergoes cleavage as translocation is occurring. However, in cases where the signal peptide is located internally, or its hydrophobic core is integrated within a longer membrane anchor domain, cleavage does not occur[15] (see later discussion). In this latter case, the "stop-transfer" sequence halts translocation and remains embedded in the membrane, functioning as the anchor for integral membrane proteins. It has been suggested that the proteinaceous ER translocation channel contains a receptor for stop-transfer sequences, the channel opening laterally to allow integration of membrane proteins.[93,102]

Protein synthesis (i.e., translation) and translocation of the protein generally occur simultaneously. Strong evidence argues against a mechanistic coupling between these two events; however, their temporal association may nonetheless play an important role — that of ensuring that nascent polypeptides maintain (or acquire) a translocation-competent conformation.[5] In mammalian cells, binding of the SRP to the signal peptide and the arrest of translation until functional insertion into the ER occurs would largely perform this important function,[15] although accessory proteins have also been implicated. SRP-like proteins have been detected in yeast. But this organism may also have a SRP-independent targeting pathway because it can survive without the SRP, and various proteins can be translocated *in vitro* in the absence of the SRP and the SRP receptor.[121] Any posttranslational translocation must occur without the SRP because the latter binds only to nascent chains attached to ribosomes.[122] It is likely that cytosolic chaperones such as 70-kDa heat-shock proteins (and probably additional proteins) function to assist proteins in maintaining a translocation-competent state.[107,123,124]

In most cases, the signal peptide is removed (in a cotranslational manner) from the nascent polypeptide chain as it emerges into the ER lumen by a signal peptidase located on the inner face of the membrane. Cleavage generally occurs at the more polar C-terminal region of the signal sequence and is thought to allow subsequent processes like protein folding and assembly to proceed normally (reviewed in Reference 4). For example, when the soybean storage protein glycinin is synthesized in an *in vitro* translation system (in the absence of ER membranes) from a synthetic mRNA corresponding to the entire glycinin coding region, the presence of the signal peptide inhibits assembly (trimerization) and results in misfolding of monomers.[125] The signal peptide has a similar negative effect on the acquisition of a functional (biologically active) conformation of α-amylase.[126]

b. Signal-Dependent Retention of Soluble Proteins in the ER Lumen

As mentioned previously, soluble resident proteins of the ER are distinguished by a carboxy-terminal tetrapeptide sequence. In mammals, these sequences are typically K/H/RDEL[59,70,127] and H/DDEL in yeasts.[127,128] Some of the more abundant soluble resident ER proteins of eukaryotes identified with these carboxy-terminal sequences include BiP, protein disulfide isomerase (PDI), and others.[129–131] In plants, the sequences have been identified at the carboxy-termini of several ER proteins (e.g., BiP, in tomato, maize, and tobacco; an auxin-binding protein in maize; and PDI in alfalfa).[17,59,132–142] The carboxy-terminal tetrapeptide sequence is necessary for retention of proteins in the ER.[70,143,144] When the sequence is deleted from an ER-resident protein (e.g., BiP), secretion is the outcome;[145] conversely, addition of the tetrapeptide to the carboxy-terminus of lysozyme (a protein that is normally secreted) or cathepsin D (a lysosomal enzyme) causes the proteins to accumulate in the ER.[70,143] Although some changes to individual amino acids can be tolerated, extending the sequence with random amino acids at the carboxy-terminus (or changing KDEL to KDAS) results in secretion of the target protein.[70,146] Thus, retention may be mediated by a specific receptor that recognizes (H/K/R)DEL only when it is present at the extreme carboxy-terminus of a protein (but see later discussion). In addition to KDEL, the carboxy-terminal sequences HDEL and RDEL are sufficient for retention in the ER and nuclear envelope of the reporter enzyme phosphinothricin acetyl transferase (PAT) in stably and transiently transformed plant cells

from a variety of species,[140,141] indicating that the plant ER retention mechanism can recognize several sequences. However, changing certain sequences within KDEL (such as KEEL, SDEL, KDDL, KDEI, and KDEV), leads to partial or complete loss of ER retention.

The nature of ER retention signals and the machinery involved in their recognition may be more complex than originally anticipated and may be distinct (in certain aspects) in different eukaryotic organisms. In addition to KDEL, HDEL, and RDEL, a variety of other sequences occur at the C-termini of ER-resident proteins in plants, yeast and mammals. Likewise, several other sequences are able to relocalize passenger proteins to the ER lumen in these eukaryotic organisms (Table 4) (reviewed in Reference 4; see references therein). Moreover, such unrelated sequences as the conserved *s*-cyclophilin-specific C-terminal region VEKPFAIAKE is sufficient to direct a secretory protein toward ER subcompartments.[147] In addition, there are examples of proteins that contain a carboxyterminal KDEL sequence (as deduced from their cDNA sequences), but are found in sites other than the ER lumen. An example is the plant auxin binding protein (ABP1) that is secreted (via the Golgi complex) to the cell surface (the plasma membrane and cell wall).[148] Interaction between the ER retention receptor and the KDEL tetrapeptide on this protein is suggested to be conditional. It may be regulated by auxin because binding of this hormone appears to change the structure of the protein (possibly its C-terminus and/or the accessibility of the KDEL retention signal), as revealed by an altered affinity of the auxin-ABP1 complex to monoclonal anti-ABP1-KDEL antibodies.[149] However, more information is needed to confirm these possibilities. PDI, containing a KDEL sequence at its C-terminal end, is not only found within the ER lumen but is also transported to the plasma membrane via the secretory pathway in rat exocrine pancreatic cells.[150] Thus, it is becoming increasingly apparent that the nature of ER localization signals is not obvious from the primary protein structure of ER-resident soluble proteins. Other approaches such as analyses of the crystal structures of R/H/KDEL-containing proteins[151,152] and nuclear magnetic resonance (NMR) analyses of a variety of peptides comprising the C-termini of ER resident proteins may be necessary to elucidate the critical features of ER localization signals.[4]

The addition of KDEL or HDEL onto the carboxy-terminus of some proteins retards transport, but is not sufficient for their absolute retention in the ER.[153,154] Retardation of export rather than total ER retention occurs with several mammalian secretory proteins that are modified at the exact carboxy-terminus to encode the sequence SEKDEL.[153] When the carboxy-terminal sequence of a plant vacuolar protein (PHA) is changed from LNQIL to LNKDEL and the derivative protein expressed in transgenic tobacco, a large proportion is localized in the ER and the nuclear envelope (that is continuous with the ER). However, a considerable amount of the PHA-KDEL is transported through the Golgi complex and reaches the protein storage vacuole/protein body.[154] Partial retention of these proteins in the ER may be due to a less than optimal display of the carboxy-terminal KDEL sequence, thus diminishing its recognition by the appropriate receptor[155] and allowing its escape from the normal retrieval mechanism (see subsequent discussion). Other structural features of the protein may be required for ER retention, and their role may not be restricted to simply ensuring optimal positioning of the tetrapeptide for receptor-mediated recognition.[4,17]

Changing the carboxy-terminus of the vacuolar pea storage protein vicilin to include KDEL (SEKDEL) results in a dramatic increase in the accumulation of vicilin in the leaves of transgenic tobacco and alfalfa.[156,157] The retention signal keeps the protein from advancing to a compartment where it could be degraded (presumably the vacuole) and results in the formation of protein-body-like inclusions. These ER-derived, membrane-bound, electron-dense structures (0.5 to 1.0 µm in diameter) contain vicilin and resemble the ER-derived protein bodies found in the endosperm cells of certain cereals such as maize and sorghum (see Section V.G.1).

Given that most proteins are transported by bulk flow, whereas certain proteins are selectively retained, it is pertinent to examine the mechanism of specific retention in the ER. The luminal proteins are not associated with a membrane-bound receptor,[59,145] nor is retention guaranteed by membrane anchoring; many membrane-bound viral proteins are transported out of the ER.[60] It appears that for soluble proteins at least, ER retention mechanisms come into play at a later point in the secretory pathway, that is, after the proteins have been transported out of the ER.[59,143] More specifically, luminal ER proteins that escape are continuously and specifically retrieved from a post-ER ("salvage") compartment (that is pre-Golgi or within the Golgi complex) by a receptor;[158] the receptor-ligand complexes are cycled back to the ER (by specialized vesicular transport; see subsequent discussion), where the KDEL-bearing proteins are released.[59] In yeast (*Saccharomyces cerevisiae*), the retrieval mechanism appears to be in the Golgi complex,[127,159] and some very elegant studies in this organism[160-162] have identified a putative receptor involved in HDEL recognition. A genetic approach was utilized to identify the essential components of the "recycling" pathway; to this end, *S. cerevisiae* mutants specifically defective in the HDEL-mediated ER retention system were isolated, allowing subsequent identification of two genes required in the process, viz., *erd1* and *erd2* (for "ER retention defective"). Deletion of the *erd1* gene causes a pleiotropic defect in part of the Golgi apparatus, which evidently results in inefficient retrieval from this organelle.[161] The *erd2* gene encodes a 26-kDa integral membrane protein that is required both for retention of ER proteins and perhaps indirectly for normal traffic of proteins through the Golgi.[160] Strikingly, the abundance of this protein determines both the efficiency and capacity of the retention system: reduced expression leads to secretion of HDEL-tagged proteins; conversely, its overexpression improves their retention (both in wild-type cells and in other mutants). Moreover, *erd2* determines the signal specificity of the retention system;[162] exchange of the *erd2* gene from *S. cerevisiae* (which only recognizes HDEL) for the corresponding gene from another yeast, *Kluyveromyces lactis* (which recognizes either HDEL or DDEL), allows equal recognition of DDEL and HDEL in *S. cerevisiae*. These observations, as well as the subcellular localization of the protein (i.e., in a post-ER, Golgi-like compartment), make it an excellent candidate for the receptor that sorts lumenal ER proteins in yeast.[160,162] The analogous mammalian protein has been localized by using epitope-tagged human *erd2*[163,164] and antibodies to the carboxy-terminal 21 amino acids of the bovine protein.[165] In normal cells, the ERD2 protein is found in the Golgi complex, but the protein is redistributed to the ER when the cells also express high levels of an appropriate ligand, such as KDEL-tagged lysozyme.[164] Thus, in mammalian cells as in yeast, the ERD2 receptor likely recycles together with the ER protein back to that compartment.[166] A cDNA clone similar in sequence and size to members of the *erd2* gene family has been identified in *Arabidopsis thaliana*.[167] The *Arabidopsis* protein exhibits 52% identity with the human homolog, and is 49% identical with the yeast counterpart. A functional role for the *Arabidopsis* ERD2 protein as a receptor for ER-retained (resident) proteins in plants is indicated by its ability to complement the lethal phenotype of the *erd2* deletion mutant of *S. cerevisiae*. In contrast, the human *erd2* homolog is unable to restore function in yeasts despite the 51% amino acid identity between the human and yeast proteins.[163] In fact, there appears

like the SEC62-SEC63 protein complex has also been suggested.[93]

Identification of potential components of the mammalian translocon has also been aided by the use of photochemicals or chemicals that cross-link nascent secretory proteins to adjacent integral ER membrane proteins. These studies implicated a 35- to 39-kDa glycoprotein (translocating chain-associated membrane [TRAM] protein) and a 34- to 37-kDa nonglycoprotein (homologous to yeast SEC61 and *Escherichia coli* SECY proteins).[114,115]

Reconstitution of detergent-solubilized rough ER proteins into translocation competent proteoliposomes allows the functional evaluation of putative translocation factors.[108,114] In mammalian cells, the SRP, the SRP receptor, SEC61, and the TRAM protein may participate directly in translocation because translocation is successful using these purified components. However, several additional stimulatory factors probably exist (perhaps mammalian homologs of the yeast proteins, SEC62, and SEC63). The TRAM protein may contact the N-terminal regions of nascent polypeptides at an early stage; a requirement for this protein depends upon the synthesized product. For example, it is essential for the transport of several precursors, but is only stimulatory for others. Further components assumed to be involved in the process include putative ribosome receptors of 34 kDa[116,117] and 180 kDa,[118] a membrane protein of 30 kDa with affinity for SRP (mp30),[119] and an unidentified ATP-binding membrane protein.[120] However, the function of these components, if any, is either disputed or not demonstrated yet (Figure 10) (see Reference 108 and references therein).

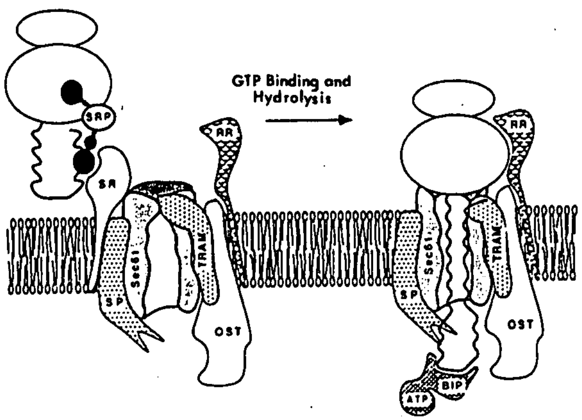

FIGURE 10. A schematic representation of the targeting and transport phases of a protein translocation reaction. The left portion of the diagram depicts SRP-dependent targeting of a ribosome to a preassembled translocation site comprised of the SRP receptor (SR), SEC61, TRAM, signal peptidase (SP), oligosaccharyltransferase (OST), and a ribosome receptor (RR). Conformational changes in Sec61p and TRAM that mediate channel gating are speculative. GTP binding and hydrolysis reactions permit SRP dissociation from the signal sequence and SRP receptor. Polypeptides traversing the channel contact TRAM and SEC61. Luminal reactions mediated by signal peptidase and oligosaccharyltransferase may inhibit reversible transport through the channel, whereas BiP may actively facilitate transport by binding the precursor as it emerges into the lumen. (From Gilmore, R., *Cell*, 75, 589, 1993. With permission from Cell Press.)

A hydrophilic protein is completely translocated across the rough ER if it is preceded by a signal that undergoes cleavage as translocation is occurring. However, in cases where the signal peptide is located internally, or its hydrophobic core is integrated within a longer membrane anchor domain, cleavage does not occur[15] (see later discussion). In this latter case, the "stop-transfer" sequence halts translocation and remains embedded in the membrane, functioning as the anchor for integral membrane proteins. It has been suggested that the proteinaceous ER translocation channel contains a receptor for stop-transfer sequences, the channel opening laterally to allow integration of membrane proteins.[93,102]

Protein synthesis (i.e., translation) and translocation of the protein generally occur simultaneously. Strong evidence argues against a mechanistic coupling between these two events; however, their temporal association may nonetheless play an important role — that of ensuring that nascent polypeptides maintain (or acquire) a translocation-competent conformation.[5] In mammalian cells, binding of the SRP to the signal peptide and the arrest of translation until functional insertion into the ER occurs would largely perform this important function,[15] although accessory proteins have also been implicated. SRP-like proteins have been detected in yeast. But this organism may also have a SRP-independent targeting pathway because it can survive without the SRP, and various proteins can be translocated *in vitro* in the absence of the SRP and the SRP receptor.[121] Any posttranslational translocation must occur without the SRP because the latter binds only to nascent chains attached to ribosomes.[122] It is likely that cytosolic chaperones such as 70-kDa heat-shock proteins (and probably additional proteins) function to assist proteins in maintaining a translocation-competent state.[107,123,124]

In most cases, the signal peptide is removed (in a cotranslational manner) from the nascent polypeptide chain as it emerges into the ER lumen by a signal peptidase located on the inner face of the membrane. Cleavage generally occurs at the more polar C-terminal region of the signal sequence and is thought to allow subsequent processes like protein folding and assembly to proceed normally (reviewed in Reference 4). For example, when the soybean storage protein glycinin is synthesized in an *in vitro* translation system (in the absence of ER membranes) from a synthetic mRNA corresponding to the entire glycinin coding region, the presence of the signal peptide inhibits assembly (trimerization) and results in misfolding of monomers.[125] The signal peptide has a similar negative effect on the acquisition of a functional (biologically active) conformation of α-amylase.[126]

b. Signal-Dependent Retention of Soluble Proteins in the ER Lumen

As mentioned previously, soluble resident proteins of the ER are distinguished by a carboxy-terminal tetrapeptide sequence. In mammals, these sequences are typically K/H/RDEL[59,70,127] and H/DDEL in yeasts.[127,128] Some of the more abundant soluble resident ER proteins of eukaryotes identified with these carboxy-terminal sequences include BiP, protein disulfide isomerase (PDI), and others.[129-131] In plants, the sequences have been identified at the carboxy-termini of several ER proteins (e.g., BiP, in tomato, maize, and tobacco; an auxin-binding protein in maize; and PDI in alfalfa).[17,59,132-142] The carboxy-terminal tetrapeptide sequence is necessary for retention of proteins in the ER.[70,143,144] When the sequence is deleted from an ER-resident protein (e.g., BiP), secretion is the outcome;[145] conversely, addition of the tetrapeptide to the carboxy-terminus of lysozyme (a protein that is normally secreted) or cathepsin D (a lysosomal enzyme) causes the proteins to accumulate in the ER.[70,143] Although some changes to individual amino acids can be tolerated, extending the sequence with random amino acids at the carboxy-terminus (or changing KDEL to KDAS) results in secretion of the target protein.[70,146] Thus, retention may be mediated by a specific receptor that recognizes (H/K/R)DEL only when it is present at the extreme carboxy-terminus of a protein (but see later discussion). In addition to KDEL, the carboxy-terminal sequences HDEL and RDEL are sufficient for retention in the ER and nuclear envelope of the reporter enzyme phosphinothricin acetyl transferase (PAT) in stably and transiently transformed plant cells

from a variety of species,[140,141] indicating that the plant ER retention mechanism can recognize several sequences. However, changing certain sequences within KDEL (such as KEEL, SDEL, KDDL, KDEI, and KDEV), leads to partial or complete loss of ER retention.

The nature of ER retention signals and the machinery involved in their recognition may be more complex than originally anticipated and may be distinct (in certain aspects) in different eukaryotic organisms. In addition to KDEL, HDEL, and RDEL, a variety of other sequences occur at the C-termini of ER-resident proteins in plants, yeast and mammals. Likewise, several other sequences are able to relocalize passenger proteins to the ER lumen in these eukaryotic organisms (Table 4) (reviewed in Reference 4; see references therein). Moreover, such unrelated sequences as the conserved *s*-cyclophilin-specific C-terminal region VEKPFAIAKE is sufficient to direct a secretory protein toward ER subcompartments.[147] In addition, there are examples of proteins that contain a carboxyterminal KDEL sequence (as deduced from their cDNA sequences), but are found in sites other than the ER lumen. An example is the plant auxin binding protein (ABP1) that is secreted (via the Golgi complex) to the cell surface (the plasma membrane and cell wall).[148] Interaction between the ER retention receptor and the KDEL tetrapeptide on this protein is suggested to be conditional. It may be regulated by auxin because binding of this hormone appears to change the structure of the protein (possibly its C-terminus and/or the accessibility of the KDEL retention signal), as revealed by an altered affinity of the auxin-ABP1 complex to monoclonal anti-ABP1-KDEL antibodies.[149] However, more information is needed to confirm these possibilities. PDI, containing a KDEL sequence at its C-terminal end, is not only found within the ER lumen but is also transported to the plasma membrane via the secretory pathway in rat exocrine pancreatic cells.[150] Thus, it is becoming increasingly apparent that the nature of ER localization signals is not obvious from the primary protein structure of ER-resident soluble proteins. Other approaches such as analyses of the crystal structures of R/H/KDEL-containing proteins[151,152] and nuclear magnetic resonance (NMR) analyses of a variety of peptides comprising the C-termini of ER resident proteins may be necessary to elucidate the critical features of ER localization signals.[4]

The addition of KDEL or HDEL onto the carboxy-terminus of some proteins retards transport, but is not sufficient for their absolute retention in the ER.[153,154] Retardation of export rather than total ER retention occurs with several mammalian secretory proteins that are modified at the exact carboxy-terminus to encode the sequence SEKDEL.[153] When the carboxy-terminal sequence of a plant vacuolar protein (PHA) is changed from LNQIL to LNKDEL and the derivative protein expressed in transgenic tobacco, a large proportion is localized in the ER and the nuclear envelope (that is continuous with the ER). However, a considerable amount of the PHA-KDEL is transported through the Golgi complex and reaches the protein storage vacuole/protein body.[154] Partial retention of these proteins in the ER may be due to a less than optimal display of the carboxy-terminal KDEL sequence, thus diminishing its

recognition by the appropriate receptor[155] and allowing its escape from the normal retrieval mechanism (see subsequent discussion). Other structural features of the protein may be required for ER retention, and their role may not be restricted to simply ensuring optimal positioning of the tetrapeptide for receptor-mediated recognition.[4,17]

Changing the carboxy-terminus of the vacuolar pea storage protein vicilin to include KDEL (SEKDEL) results in a dramatic increase in the accumulation of vicilin in the leaves of transgenic tobacco and alfalfa.[156,157] The retention signal keeps the protein from advancing to a compartment where it could be degraded (presumably the vacuole) and results in the formation of protein-body-like inclusions. These ER-derived, membrane-bound, electron-dense structures (0.5 to 1.0 µm in diameter) contain vicilin and resemble the ER-derived protein bodies found in the endosperm cells of certain cereals such as maize and sorghum (see Section V.G.1).

Given that most proteins are transported by bulk flow, whereas certain proteins are selectively retained, it is pertinent to examine the mechanism of specific retention in the ER. The luminal proteins are not associated with a membrane-bound receptor,[59,145] nor is retention guaranteed by membrane anchoring; many membrane-bound viral proteins are transported out of the ER.[60] It appears that for soluble proteins at least, ER retention mechanisms come into play at a later point in the secretory pathway, that is, after the proteins have been transported out of the ER.[59,143] More specifically, luminal ER proteins that escape are continuously and specifically retrieved from a post-ER ("salvage") compartment (that is pre-Golgi or within the Golgi complex) by a receptor;[158] the receptor-ligand complexes are cycled back to the ER (by specialized vesicular transport; see subsequent discussion), where the KDEL-bearing proteins are released.[59] In yeast (*Saccharomyces cerevisiae*), the retrieval mechanism appears to be in the Golgi complex,[127,159] and some very elegant studies in this organism[160–162] have identified a putative receptor involved in HDEL recognition. A genetic approach was utilized to identify the essential components of the "recycling" pathway; to this end, *S. cerevisiae* mutants specifically defective in the HDEL-mediated ER retention system were isolated, allowing subsequent identification of two genes required in the process, viz., *erd1* and *erd2* (for "ER retention defective"). Deletion of the *erd1* gene causes a pleiotropic defect in part of the Golgi apparatus, which evidently results in inefficient retrieval from this organelle.[161] The *erd2* gene encodes a 26-kDa integral membrane protein that is required both for retention of ER proteins and perhaps indirectly for normal traffic of proteins through the Golgi.[160] Strikingly, the abundance of this protein determines both the efficiency and capacity of the retention system: reduced expression leads to secretion of HDEL-tagged proteins; conversely, its overexpression improves their retention (both in wild-type cells and in other mutants). Moreover, *erd2* determines the signal specificity of the retention system;[162] exchange of the *erd2* gene from *S. cerevisiae* (which only recognizes HDEL) for the corresponding gene from another yeast, *Kluyveromyces lactis* (which recognizes either HDEL or DDEL), allows equal recognition of DDEL and HDEL in *S. cerevisiae*. These observations, as well as the subcellular localization of the protein (i.e., in a post-ER, Golgi-like compartment), make it an excellent candidate for the receptor that sorts lumenal ER proteins in yeast.[160,162] The analogous mammalian protein has been localized by using epitope-tagged human *erd2*[163,164] and antibodies to the carboxy-terminal 21 amino acids of the bovine protein.[165] In normal cells, the ERD2 protein is found in the Golgi complex, but the protein is redistributed to the ER when the cells also express high levels of an appropriate ligand, such as KDEL-tagged lysozyme.[164] Thus, in mammalian cells as in yeast, the ERD2 receptor likely recycles together with the ER protein back to that compartment.[166] A cDNA clone similar in sequence and size to members of the *erd2* gene family has been identified in *Arabidopsis thaliana*.[167] The *Arabidopsis* protein exhibits 52% identity with the human homolog, and is 49% identical with the yeast counterpart. A functional role for the *Arabidopsis* ERD2 protein as a receptor for ER-retained (resident) proteins in plants is indicated by its ability to complement the lethal phenotype of the *erd2* deletion mutant of *S. cerevisiae*. In contrast, the human *erd2* homolog is unable to restore function in yeasts despite the 51% amino acid identity between the human and yeast proteins.[163] In fact, there appears

to be several distinctive features of the ER-retention mechanisms of yeast (e.g., *S. cerevisiae*) vs. those of mammals.

In *S. cerevisiae*, there is a strict requirement for a C-terminal HDEL sequence for ER retention. In animals and plants, many different C-terminal sequences on ER-resident proteins are tolerated, such as HDEL, RDEL, and KDEL (Table 4; see earlier discussion). Moreover, the monoclonal antibody ID3 (which recognizes the C-terminal portion of mammalian PDI) does not recognize HDEL-containing yeast BiP,[155] nor any other yeast proteins.[4,168] However this antibody is capable of recognizing an important structure of the ER localization signal in a family of plant and mammalian ER-resident proteins. In some ways then, the ER retention mechanisms of plants exhibit characteristics somewhat intermediate between those of animals and those of yeast.

The plant ERD2 protein may be an example of a functional link between the other two groups of eukaryotic organisms. A binding specificity similar to the human ERD2 counterpart is suggested and it contains conserved sequences (e.g., Asp[176]) found to be important for recycling of the human receptor (Asp[193]). However, it can also function in yeast.[167] It is expected that the differences between the *erd2* homologs from plants and animals with respect to their functional activity in yeast are a result of differences in critical amino acid sequences of the two proteins. Future prospects for mapping the functional domains of the ERD2 proteins include mutational analyses and construction of chimeric proteins using the different *erd2* genes in conjunction with complementation tests, binding, and localization studies.[167]

Another pertinent question that has recently been addressed is how the ER membrane is maintained in the face of a heavy flow of vesicular traffic towards the Golgi stack.[169,170] The ER is a dynamic network of tubular membranes that extend along microtubules, continuously breaking, fusing, and rearranging.[171] Recent studies utilizing the antifungal antibiotic brefeldin A suggest that there is an intermediate compartment to the ER transport pathway involving microtubules that potentially could restore membrane components and escaped proteins to the ER.[169,170] In the presence of the drug, the Golgi complex breaks down and appears to merge with the ER;[172-174] consequently, both components now interact with microtubules in the same way. Secretory and (H/K)DEL-tagged proteins may normally be sorted in the intermediate (salvage) compartment, such that the latter are returned via a retrograde pathway involving microtubules. Membrane vesicles destined to return to the ER may carry or acquire proteins that enable them to interact with microtubules; these proteins may normally be excluded from vesicles involved in nonselective (bulk-flow) transport during sorting in the salvage compartment.[15,169,170] Because the retrograde pathway into the ER depends on microtubules, in contrast to the anterograde pathway out of the ER, this provides a potential means by which cells can regulate membrane transport along these two pathways (Figure 11).

The ERD2 protein in yeast not only functions as a receptor, but also is required for normal vesicular traffic through the Golgi complex; these two functions may be related.[160] For example, ERD2 may be required for the formation of the specialized vesicles involved in retrograde transport; whether it interacts directly with microtubules remains to be determined. In mammalian cells, proteins localized in a pre-Golgi (or Golgi) intermediate compartment may play a role similar to that of ERD2 (e.g., as microtubule attachment proteins). Some (but not all) ER membrane proteins normally escape to the Golgi complex and require retrieval; recycling of the SEC12 protein (see later discussion) and perhaps other membrane proteins involved in vesicular traffic and membrane flow is also suggested.[175] ERD2 and equivalent mammalian proteins might also be involved in maintaining the supply of such components in the compartments from which vesicles bud. A failure to retrieve these membrane proteins could reduce the flow of the secretory pathway to a trickle.[160] Whether a similar retrograde pathway and retrieval mechanism exist in plant cells remains to be determined. Studies using brefeldin in plants are in their infancy and we clearly need to know more about the specific effects of this inhibitor on the plant Golgi complex and ER both at the morphological level and at the molecular level.[176,177]

Brefeldin inhibits the secretion of proteins[148,178] and noncellulosic polysaccharides[179] and the transport of a vacuolar protein, PHA.[180] Evidence supporting a retrograde pathway from the Golgi complex to the ER is indicated by changes in the quantity of various glycosylated forms of PHA in transgenic tobacco cells following treatment with brefeldin that appear to be consistent with a redistribution of Golgi enzymes involved in glycan processing to the ER.[180] However, redistribution of the Golgi membrane marker JIM84 into the ER does not occur in maize and onion root cells,[3,177,181] and immunofluorescence studies fail to show tubular structures emerging from the Golgi complex and directed to the ER. Several features of the plant Golgi complex make it unique and distinct from the Golgi of animals, including separate stacks, wall matrix synthesis, and lack of fragmentation during plant cell division. There even may be structural and functional cell type-specific differences in the organization of the plant Golgi stacks,[83] and these are reflected in a differential sensitivity to brefeldin (see Reference 177 and references therein). It is apparent that more systematic studies need to be undertaken before conclusions can be reached regarding a retrograde transport pathway from the plant Golgi complex to the ER.

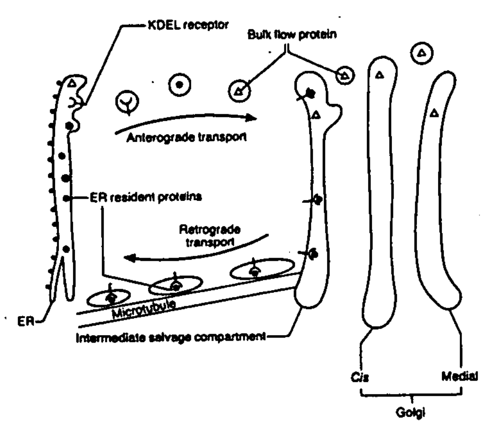

FIGURE 11. Protein recycling between the ER and Golgi. Proteins are transported in vesicles from the ER to the salvage compartment, where the KDEL receptor carries proteins bound back to the ER by a retrograde transport pathway in which vesicles travel along microtubules. c. Targeting Signals for Membrane Proteins of the Secretory Pathway

I. Topology of Integral Membrane Proteins

The membranes surrounding the organelles of the secretory pathway represent highly specialized compartments; most of the functions of membranes are carried out by the select group of proteins embedded within, or otherwise associated with, the lipid bilayer. (For further discussion on the topography of membrane proteins, see References 10 and 97). After translocating partly across the ER membrane, these proteins are transported to further compartments of the secretory pathway (along with luminal proteins) in the membranes of the transport vesicles. Transmembrane proteins are either single-pass (i.e., they span the

phospholipid bilayer only once) or multi-pass (i.e., they span the bilayer multiple times). Topology is established when the protein first assembles into the membrane. For plasma membrane proteins and membrane proteins of internal organelles of the secretory pathway, topology is adopted at the ER membrane; subsequent transport to other organelles or to the cell surface is mediated by vesicles in which protein topology remains unchanged. Thus, a domain of a membrane protein that remains cytoplasmic at the ER membrane is still cytoplasmic after transport of the protein to the organelle or plasma membrane. Proteins are also specifically oriented within the membranes of mitochondria, chloroplasts, and other organelles after synthesis in the cytoplasm.[10]

The orientation of single-pass transmembrane proteins depends on the positions of the signal peptide and the hydrophobic stretches of the protein that will span the membrane after the protein is oriented. As shown in Figure 12 and Table 5, membrane proteins are classified into three groups (I, II, and III) based primarily on how they are oriented in the membrane and whether they contain a (conventional) signal peptide. Not all membrane proteins pass through the lipid bilayer; some become attached to membranes by a specific covalent attachment of fatty acids, prenyl groups, or inositol glycolipids.[10,94]

ii. Localization Signals of Membrane Proteins

Proteins destined to reside in the membranes of the ER cisternae require retention signals; however, much less is known about the nature of these ER membrane localization signals. The C-terminal KDEL/HDEL signal used for the retrieval of lumenal ER proteins from the Golgi complex (salvage compartment) is present on the lumenal domains of two yeast type II membrane proteins (the products of the *sec20* and *sed4* genes) and appears to be involved in their retrieval back to the ER.[182] However, other retention mechanisms exist. Some mammalian ER membrane proteins (e.g., glucuronosyl transferase) contain a double lysine motif in the C-terminal cytoplasmic tail (KKXX, KXKXX, or a similar sequence), which functions to ensure retrieval from the Golgi complex back to the ER.[183] A double lysine motif is also present in the C-terminal sequence of a plant gene, omega-3 desaturase from *Arabidopsis*.[184] The E19 protein of adenovirus is a membrane-anchored resident ER polypeptide that has a short tail protruding into the cytoplasm. A small stretch of amino acids on this exposed tail (i.e., the last C-terminal six residues, DEKKMP) is necessary and sufficient for retention in the ER;[72] the last three amino acids are conserved in E19 proteins of several adenoviruses.[185] However, this sequence is not conserved in other ER membrane proteins. Other positively charged amino acids within the C-terminus might constitute retention signals for ER membrane proteins, as indicated by the C-terminal sequence of calnexin (SPRNRKPRRE), an abundant ER type I membrane protein of mammalian cells.[186] However, the ER retention signal of the CD3ε chain of the T-cell receptor appears to be completely unrelated to the lysine motif.[187] Still other retention signals have been identified, primarily of viral proteins in infected animal cells. For the rotovirus VP7 protein (a 37-kDa glycoprotein), the signal peptide, together with the first 60 amino acid residues of the mature protein, forms the retention signal,[188] although the mechanism of retention is not yet understood. A N-terminal amino acid sequence is also responsible for the retention of a hepatitis B virus type II membrane glycoprotein.[189] Thus, the mechanisms for localization of ER membrane proteins are diverse, and no obvious consensus sequence can be defined. Moreover, both cytoplasmic and luminal domain recognition is involved. However, it is clear that a retention mechanism operating solely by salvaging lost or escaped proteins is not sufficient to explain the available evidence. For example, careful examination of the oligosaccharides of some ER membrane proteins indicates that they do not leave the ER.[190,191] Furthermore, removal of the retrieval signal from ER proteins often causes them to be transported only very slowly, suggesting that there is additional retention information elsewhere in the protein.[70,183] Surprisingly, a KKXX sequence is also found in ERGIC 53, a marker protein for an intermediate compartment between the ER and Golgi complex.[192] Presumably, this protein lacks the necessary structural determinants for ER retention, causing its rapid export from the ER.

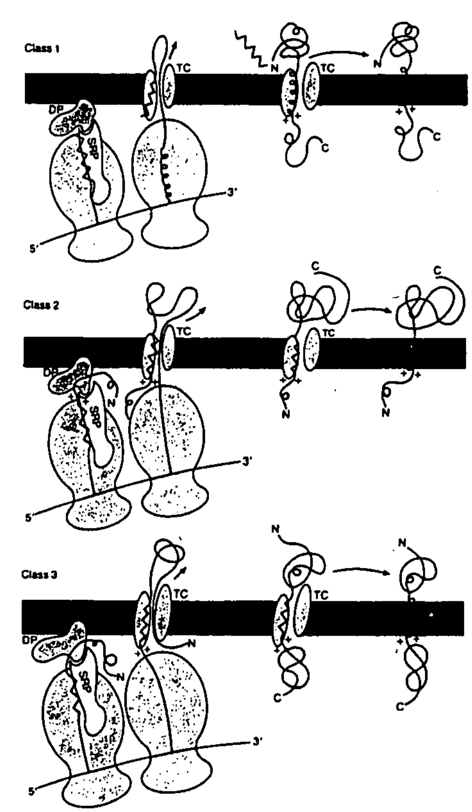

FIGURE 12. Mechanisms of assembly of single transmembrane proteins. The three different modes of assembly for proteins involve interactions of the signal sequence or stop-transfer sequence with signal recognition particle (SRP), docking protein (DP), and the translocation complex (TC). (From Austen, B. M. and Westwood, O. M. R., *Protein Targeting and Secretion*, Oxford University Press, Oxford, 1991. With permission from Oxford University Press.)

Retention signals for localization in the Golgi membrane have been identified for several *medial-* and *trans-*Golgi enzymes. They are all type II proteins with a short N-terminal cytoplasmic tail followed by a single transmembrane domain (reviewed in Reference 7). This transmembrane domain (with a few amino acids on either side) is both necessary and sufficient for Golgi localization. The mechanism is highly specific; when the membrane spanning domain of a reporter protein is replaced by that of the Golgi protein, the hybrid protein not only resides in the Golgi complex, but

TABLE 5
Topography of Single-Pass Transmembrane Proteins and Their Mechanisms of Insertion Into the Membrane[a]

Type	Examples	Characteristics
I	Glycophorin A VSV-G M6P receptor	Signal sequence interacts with SRP; subsequent stop-transfer sequence halts translocation; signal sequence cleaved; oriented with N-termini on luminal side; C-termini on cytoplasmic side
II	Ca^{2+}-ATPase Lens MP26	Lacks cleavable signal peptide; stop-transfer sequence doubles as signal sequence that interacts with SRP and enters translocation site; have higher concentration of positively charged residues on N-terminal side of stop-transfer sequence C-termini reside in lumen, N-termini on cytoplasmic side
III	Cytochrome P-450 Epoxide hydrase	Mechanism of insertion as above; have a number of positively charged residues on C-terminal side of stop-transfer sequence; N-termini in lumen; C-termini in cytoplasm

[a] Reviewed in Reference 10; see also Figure 13. (VSV-G: G-protein of vesicular stomatitis virus; M6P receptor: mannose-6-phosphate receptor.)

also in the correct cisternae.[193-195] In contrast to the proteins of the TGN (see later discussion) there is little evidence that the enzymes of the Golgi stack recycle through later compartments. On the other hand, a resident of the TGN, TGN38, contains two non-overlapping signals, one mediating retrieval and the other mediating retention.[196] A tyrosine-based motif in the cytoplasmic domain acts as the retrieval signal, returning the protein from the cell surface to the TGN. The second signal is within the membrane spanning domain and is necessary for retention in the TGN.

Selective retention mechanisms mediated by transmembrane domains are likely to involve some interaction within the membrane itself. One possibility is that retention results from the formation of protein aggregates (reviewed in Reference 7). For example, some of the *medial*-Golgi enzymes (*N*-acetylglucosaminyl transferase I and mannosidase II) can associate with each other *in vivo*, suggesting that they may form complexes that are too large to be transported. Retention could be improved further by binding of the proteins to an intercisternal matrix that would effectively exclude them from regions where vesicle buds form.[194] However, whereas the transmembrane domain is sufficient for retention, it does not appear to be sufficient for aggregation (i.e., the structural requirements for retention and complex formation are somewhat different). Aggregation or matrix attachment, then, may not be the primary retention mechanism for Golgi proteins. However, such interactions may well improve retention efficiency and ensure that enzymes required in the same compartment are co-localized; they may also play a role in stabilizing and organizing the stacked structure of the Golgi complex.[7,194] An alternative view is that the retention of Golgi enzymes is a consequence of the general physical properties of the transmembrane protein domains and the membrane in which they lie.[197] Here, the length of the transmembrane domain, rather than any specific amino acid sequence, is the critical feature for sorting. The membrane-spanning domains of Golgi proteins are consistently shorter (typically 17 residues long), and have a greater proportion of phenylalanine residues than those of plasma membrane proteins (typically 21 residues long). Moreover, replacement of the transmembrane domain of sialyltransferase, a Golgi-specific protein, with 17 leucine residues does not interfere with its retention in the Golgi complex, but extension of the replacement amino acid sequence to 23 leucines allows transport to the cell surface.[198] Thus, a model has emerged that views the sorting of Golgi

proteins as a consequence of the sorting of membrane lipids, with Golgi and plasma membrane proteins adapted to bilayers of different thicknesses. Furthermore, the polarity of the Golgi complex is thought to arise naturally from a gradient of lipid composition; the stable identity of this organelle being maintained by a simple feedback loop: protein content controls lipid composition, which in turn controls protein content. Before this model can be substantiated, more information is needed concerning the mechanisms and consequences of lipid sorting as well as targeting molecules involved in vesicular targeting[7] and selection of vesicle content (see later discussion).

There is information on the topogenic sequences of internal membrane proteins that are incorporated into the membranes (ER, Golgi, tonoplast, plasma membrane) of the secretory system of plant cells. Analysis of the amino acid sequences of three proteins that transit the secretory pathway (e.g., a plasma membrane proton-translocating ATPase, a vacuolar H^+-pyrophosphatase, and a seed-specific tonoplast protein) reveals several membrane-spanning domains in each protein.[199-202] The tonoplast intrinsic protein (TIP) of bean seeds (α-TIP) is synthesized on the rough ER, and its transport to the tonoplast is mediated by the secretory system; its C-terminal transmembrane domain may contain sufficient information for transport to the tonoplast.[203] However, the possibility that the signal-independent default pathway for membrane proteins leads to the tonoplast (rather than to the plasma membrane) is being investigated (see later discussion).[180]

Interestingly, synthesis of TIP in seeds does not appear to be related (in a quantitative manner) to storage protein deposition, and TIP is not found in leaves that accumulate vegetative storage protein. A role as a solute transporter in seeds has been suggested for this protein;[200] alternatively, its developmental regulation is indicative of a physiological function during late seed maturation, perhaps in the acquisition of desiccation tolerance.[204] Recently, the function of γ-TIP has been elucidated — that of forming water channels involved in osmoregulation.[39] The vacuolar H^+-ATPases are thought to be an integral part of the organelles of the endomembrane system in plants (reviewed in References 205 through 207); acidification of these compartments by the enzyme may be essential for protein sorting in plants, similar to its role in animal and yeast cells (see later discussion).

C. Membrane Growth and Lipid Transfer

As mentioned previously, different types of plant cells contain different proportions of various membranes (reviewed in Reference 50), and this has raised questions about the mechanisms that control membrane growth and changes in membrane lipid content/composition, requiring the movement of lipids between organelles. There may be two mechanisms involved in the selective transfer of lipid between organelles of the secretory pathway (e.g., the ER, Golgi, and plasma membrane), resulting in different membrane lipid compositions.[50] These include the transfer of lipid in the membranes of ER-derived vesicles that fuse with the acceptor membrane[66] and the transfer of lipid monomers through the cytoplasm as either free monomers or via protein-facilitated transport. Lipid-transfer proteins (LTPs) were originally defined by their ability to transfer specific or several different phospholipids between membrane fractions *in vitro*, but their *in vivo* function(s) is poorly understood.[208] A LTP in yeast (the phosphatidyl-inositol-specific LTP, or pi LTP) may be involved in transferring lipid from the Golgi complex back to the ER; a temperature-sensitive mutant deficient in this protein (and in the formation of secretory vesicles) accumulates very large amounts of Golgi membrane, and the ER virtually disappears.[209] A role for the nonspecific LTPs of plants as catalysts for a similar transfer of lipid between membranes is far from established. For example, the subcellular location of one such protein, a nonspecific LTP of *Arabidopsis* that is localized to the cell wall,[210] is inconsistent with a role in intracellular lipid transfer. Analysis of transgenic plants in which the amount of nonspecific LTP has been greatly reduced by expression of an antisense gene construct[211] may aid in elucidating the *in vivo* function of plant nonspecific LTPs.[50]

If nonspecific LTPs play a role in intracellular lipid transfer, what is their mechanism of action? One possibility is that these proteins

preferentially abstract lipid from a membrane of high lipid/protein ratio and release lipid into membranes with a low lipid/protein ratio.[50] It is further speculated that membrane growth is controlled via a mechanism that enables cells to sense the lipid/protein ratio of its membranes. Integral membrane proteins, which are often specific to a particular membrane and are regulated developmentally and by environmental cues, have been pinpointed as the important sensor mechanism. According to this model, then, membrane growth is triggered by the synthesis of membrane proteins. Insertion of protein into existing membranes triggers the demand for lipid that is either synthesized within the membrane or transferred from the ER by a nonspecific LTP or an equivalent mechanism. Other regulatory factors to consider are protein turnover and the possibility that changes in the amount of protein may induce changes in the composition of various lipids.[50]

D. Cotranslational and Posttranslational Modifications Along the Secretory Pathway

Many proteins that are transported along the secretory pathway in plant cells undergo extensive modifications, including glycosylation, folding, oligomer assembly, and proteolytic processing. Some of these processes have been studied in relation to their role in transport efficiency, protein stability, and protein targeting per se.

1. Glycosylation

Glycosylation is a modification that many vacuolar and extracellular proteins undergo *en route* to their target organelles. In the process known as O-linked glycosylation, the oligosaccharide or glycan of the mature glycoprotein is linked to the oxygen of either a serine or threonine amino acid residue. In N-linked glycosylation, the glycan is linked to the amide nitrogen of an asparagine residue. O-linked glycans are important components of hydroxyproline-rich glycoproteins and arabinogalactan proteins, two major classes of cell-wall proteins (see earlier discussion). In addition to O-glycosylating serine and theonine residues, plants frequently attach oligomeric arabinoside chains to hydroxyproline residues of proteins; both these modifications are carried out in the Golgi complex.[212,213] As in animal systems, the O-linked glycans of cell-wall proteins may be of critical importance for producing stiff and extended protein conformations.[214,215]

In their mature state, vacuolar or extracellular and membrane glycoproteins often have both high mannose and complex N-linked glycans (Figure 13) (reviewed in References 17, 29, and 216 through 219). Glycans of the high-mannose type (e.g., $Glc_3Man_9GlcNAc_2$) are assembled on dolichol pyrophosphate lipid carriers in the ER lumen. These are transferred (in a cotranslational manner) to specific Asn residues (of the acceptor sequence Asn-X-Ser/Thr) on nascent polypeptides by oligosaccharyl transferase[220] (reviewed in Reference 221). Two ER-resident enzymes (Glucosidases I and II) subsequently remove the three terminal glucose residues from the high-mannose glycans on most proteins[222] (a notable exception is α-mannosidase of jackbean cotyledons, which escapes this modification).[223]

The dolichol pyrophosphate lipid carrier is embedded in the lipid bilayer, and the high-mannose glycan is built up by the stepwise addition of individual monosaccharides using sugar nucleotides as the donors. In mammalian cells and yeast, stepwise addition of sugars to yield the structure $Man_{3-5}GlcNAc_2$-PP-dolichol is thought to occur on the cytosolic face of the ER membrane; following translocation of the entire intermediate to the luminal face, the subsequent addition of sugars is completed (Figure 14) (reviewed in Reference 224). The product, dolichol PP-$GlcNAc_2Man_9$ is formed by the addition of four mannose residues on the luminal side; here, the direct sugar donors are not guanosine diphosphate (GDP)-Man, (a membrane-impermeable substrate), but dolichol-P-mannose, the latter being synthesized on the cytosolic side of the membrane from GDP-Man and then translocated into the lumen. Dolichol-PP-$GlcNAc_2Man_9$ must be glucosylated before it can serve as an oligosaccharide substrate for nascent polypeptide chains; the donor for this reaction is dolichol-P-glucose, which is itself synthesized from UDP-Glc and dolichol-P. The catalytic subunit of the plant enzyme Glc-P-dolichol synthase (a polypeptide of

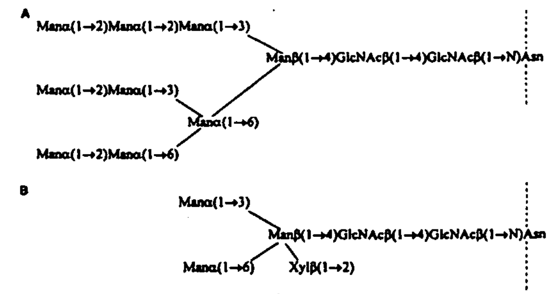

FIGURE 13. The glycan side chains of glycoproteins. (A) A typical Asn-linked simple or high mannose oligosaccharide side chain (soybean agglutinin). (B) Probable structure of one version of a modified or complex oligosaccharide side chain of phaseolin. (From Bewley, J. D. and Black, M., *Seeds. Physiology of Development and Germination*, 2nd ed., Plenum Press, New York, 1994. With permission from Plenum Press.)

39 kDa) has been purified from mung bean microsomes.[225]

The enzyme oligosaccharyl transferase that is responsible for transfer of the high-mannose chain to the Asn residue of the growing polypeptide chain is thought to be part of an integral membrane protein complex, possibly comprised of ribophorins I and II and a polypeptide of 48 kDa.[226] One complex occurs at each protein translocation site (translocon) in the ER membrane; this may play a role in maximizing the efficiency (and accuracy) of glycosylation, allowing rapid continuous monitoring of the nascent and growing polypeptide chain for the presence of glycosylation sites.[4,226] As mentioned previously, elaboration of the glycan moiety to the protein normally occurs cotranslationally. The coupling of glycosylation with protein synthesis/translocation ensures an efficient transfer of the oligosaccharide as a result of the close proximity of the transferase complex in the ER membrane. Also, as will be discussed, glycosylation influences protein conformation. Thus, it may be important that glycosylation occur early in the pathway of translocation to ensure that the protein will subsequently fold and assemble properly, rendering it competent for transport out of the ER lumen (see later discussion).

Presence of the consensus tripeptide sequence Asn-X-Ser/Thr within a polypeptide is not sufficient to guarantee glycosylation; in many cases, the site is not glycosylated or is glycosylated with low efficiency (reviewed in Reference 4). As an example, the bean storage protein phaseolin has two glycosylation sites; the one closest to the N-terminus is always glycosylated, but utilization of the second site is not efficient.[218,227] The pattern of glycosylation must be characteristic of the protein because it generally does not depend on the cell type (or host organism) in which it is synthesized. When phaseolin is expressed in a variety of heterologous hosts (e.g., yeast, *Xenopus* oocytes, or tobacco protoplasts) it is produced as a mixture of partially and fully glycosylated polypeptides.[228-230] It is likely that the cotranslational folding of the polypeptide luminal parts (i.e., those already translocated) determines whether a subsequent site in the polypeptide chain will be a substrate for glycosylation by restricting access of the oligosaccharyl transferase to certain glycosylation sites. Supporting evidence comes from studies using agents that negatively affect folding; under these conditions, a site normally unused or inefficiently utilized *in vivo* becomes fully glycosylated.[231] Likewise, destruction of the

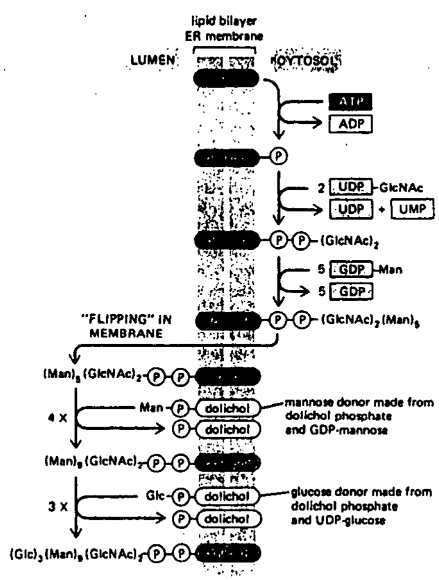

FIGURE 14. Synthesis of the lipid-linked oligosaccharide that is transferred to asparagine residues of nascent polypeptides on the luminal side of the ER membrane. The oligosaccharide is assembled sugar by sugar onto the carrier lipid dolichol (a polyisoprenoid), to which the first sugar is linked by a pyrophosphate bridge. This high-energy bond activates the oligosaccharide for its transfer from the lipid to an asparagine side chain. The synthesis of the oligosaccharide starts on the cytosolic side of the ER membrane and continues on the luminal face after the Man_5-$GlcNAc_2$ lipid intermediate is flipped across the bilayer. All of the glycosyl transfer reactions on the luminal side of the ER involve transfers from dolichol-P-glucose and dolichol-P-mannose. These activated, lipid-linked monosaccharides are synthesized from dolichol phosphate and UDP-glucose or GDP-mannose (as appropriate) on the cytosolic side of the ER, and are then thought to be flipped across the ER membrane. Abbreviations: GlcNAc, *N*-acetylglucosamine; Man, mannose; Glc, glucose. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 2nd ed., Garland Publishing, New York, 1989. With permission from Garland Publishing.)

first glycosylation site of phaseolin by site-directed mutagenesis increases the efficiency of glycosylation at the second site *in vivo*.[230] Thus, an oligosaccharide chain on the portion of the polypeptide already synthesized can affect cotranslational glycosylation, either by directly masking a second subsequent glycosylation site or, indirectly, through an effect on folding.[4]

Interestingly, when a phaseolin mutant that is defective in its assembly into trimers is synthesized in *Xenopus* oocytes, it is retained in a pre-Golgi compartment (unlike the wild-type protein) and undergoes posttranslational glycosylation at the second site.[229] Posttranslational glycosylation of the ER-retained mutant may have occurred due to its prolonged residence in the ER and a better exposure of the consensus sequence in monomers than in trimers. There is likely a complex interplay between folding, assembly, and glycosylation to ensure that a newly synthesized protein acquires a functional conformation after translocation into the ER lumen.[4]

Following cotranslational transfer of the glycan onto the nascent protein, removal of the three Glc residues in the ER results in the formation of a of typical high-mannose glycan ($Man_9[GlcNAc]_2$). This may be further modified later in the secretory pathway (in the Golgi complex) (i.e., converted from a high-mannose glycan to a complex glycan as a result of the sequential action of several glycosidases and glycosyl transferases).[216,217] The complex glycans of plant glycoproteins differ substantially from those of mammalian glycoproteins; most notable is the lack of sialic acid and the presence of a xylose residue β-1,2 linked to β-mannose of the core. However, plant complex glycans may share some similar structural features with those of insects and molluscs.[232] In plants, complex glycans are characterized by fucose and xylose sugar residues attached to the proximal GlcNAc and core mannose residues, respectively. This modification renders the glycoprotein resistant to the *Streptomyces* enzyme endoglycosidase H; hence, this characteristic has been used as evidence for passage through the Golgi complex.[17]

As in animal cells, the posttranslational processing of N-linked glycans of plant proteins occurs in a *cis*-to-*trans* direction.[213,233] Progress has been made toward characterizing and localizing enzymes involved in converting N-linked glycans to complex glycans.[213] However, a clear-cut biochemical fractionation of *cis*-, *medial*-, and *trans*-Golgi cisternal membranes from plant cells has not been obtained to date.[222,234] To overcome some of the limitations associated with biochemical fractionation, immunolabeling techniques, in conjunction with quantiative electron microscopy, have been used to determine in which Golgi cisternae specific sugars are added to glycoproteins and polysaccharides.[235,236] This approach became feasible with the development of methods for the immunolabeling of high-pressure frozen/freeze-substituted cells in which the morphology of the Golgi stacks is preserved to a much greater extent than in conventionally fixed samples. Antibodies specific for the xylose residues β1,2-linked to mannose and for fucose α1,3-linked to GlcNAc have localized enzymes involved in glycan processing in suspension cultured sycamore cells. β1,2-xylosyl transferase is located mainly in *medial*-Golgi cisternae, whereas the α1,3-fucosyl transferase is confined primarily to the trans-Golgi cisternae and the TGN, indicating that addition of fucose occurs after addition of xylose.[213] Further biochemical and immunocytochemical studies (with antibodies specific to the sugars of complex glycans) will help to elucidate the compartmentalization and sequence of the processing pathways in the Golgi complex.

Apparently, glycans must be readily accessible to the appropriate enzymes in the Golgi apparatus; when inaccessible, they remain in a high-mannose form as the protein moves through the Golgi complex.[237] A large variety of complex structures may be formed on mature glycoproteins and high-mannose chains and different complex chains may be found on the same polypeptide.[238-240] Moreover, the final structure of a complex chain may be cell-type dependent due to some cell-specific differences in the set of Golgi processing enzymes.[4,239] In general, the complex glycans of vacuolar proteins tend to be very similar (Figure 13), and are closely related to ($[Xyl]Man_3[Fuc]GlcNAc_2$), whereas those of secreted proteins are very heterogeneous and fairly large;[239] these differences are apparent even in the same plant cells. The larger oligosaccharides have additional sugars, such as *N*-acetylglucosamine, galactose, and fucose, attached to the nonreducing ends of the molecules.[241,242] Some of the heterogeneity is generated by the action of glycosidases located at sites beyond the Golgi complex (e.g., in the cell wall). In carrot suspension cultured cells, a 52- to 54-kDa medium protein is secreted with large homogeneous complex glycans; the heterogeneity originates from slow processing after secretion. In the same cells, the complex glycans of

cell wall β-fructosidase are processed before the enzyme is integrated into the cell wall.[239] Vacuolar proteins leave the Golgi complex with one or two terminal *N*-acetylglucosamine residues that are removed soon after arrival at their final destination, giving rise to homogeneous complex glycan structures.[218,243]

What are the general roles of N-linked glycosylation and glycan processing? The role of N-linked glycans in the transport and targeting of proteins to the plant cell vacuole has been examined (reviewed in Reference 17), and the available evidence indicates that glycans do not contain vacuolar targeting information. Not all vacuolar proteins are glycoproteins (e.g., 11S globulins, legumin, glycinin, and others); moreover, some glycosylated precursors lose their glycans during posttranslational processing *en route* to the vacuole (e.g., concanavalin A, wheat germ agglutinin, and β-glucanase).[244-246] Tunicamycin inhibits N-linked glycosylation in the ER by interfering with the elaboration of glycans (GlcNAc-1-P) onto the dolichol lipid intermediate.[247] However, this antibiotic generally does not cause missorting of (normally glycosylated) vacuolar proteins, including pea vicilin and bean PHA.[248,249]

Elimination of glycosylation sites by site-directed mutagenesis has been used as a direct approach to study the role of glycosylation in protein transport. Elimination of the glycosylation sites of three plant vacuolar proteins by this means (viz., PHA, patatin, and barley lectin) does not lead to mistargeting of the unglycosylated proteins in a heterologous host plant system.[82,250,251] Thus, in contrast to proteins of the animal lysosome, in which glycans play a pivitol role in their targeting (see earlier discussion), the glycans of plant vacuolar proteins do not contain targeting information. Such is also the case for glycans of yeast vacuolar proteins.[252]

Whereas tunicamycin inhibits the biosynthesis of the N-linked glycans resulting in nonglycosylated proteins, a second class of inhibitors (e.g., the alkaloids castanospermine, deoxymannojirimycin, and swainsonine) inhibit the processing of N-linked glycans.[253,254] More specifically, castanospermine inhibits glucose trimming in the ER; in relation to trimming reactions involved in the conversion of glycans to the complex form in the Golgi, deoxymannojirimycin inhibits the first enzyme (mannosidase I) in the pathway, and swainsonine inhibits the third glycosidase in the pathway (mannosidase II).[254] Studies with these latter inhibitors of glycan processing indicate that complex glycans are not necessary for secretion. Indeed, glycoproteins are secreted normally in sycamore cell suspensions and accumulate to normal levels when Golgi processing is inhibited.[255] The lack of a role for complex glycans in transport is supported by studies of a mutant of *A. thaliana* that is blocked in the conversion of high mannose to complex glycans due to an absence of the first glycosyltransferase enzyme in the pathway, *N*-acetylglucosaminyl transferase.[256] The mutant plants develop normally under several environmental conditions. Only further work will clarify whether this particular Golgi-mediated modification is critical for a small subset of glycoproteins elicited by a specific biotic or abiotic stress.[256]

Although N-linked glycans do not play a role in targeting per se, they may play a fundamental role in promoting correct protein folding and, as a consequence, enhance protein stability (e.g., via protection against proteolysis). Treatment of suspension-cultured plant cells with tunicamycin leads to a cessation of protein glycosylation and a decline in the accumulation of newly synthesized proteins in the culture medium and cell wall;[255-258] this is due primarily to an effect upon protein stability and not on protein synthesis.[259] Elimination of the glycosylation sites of phaseolin (a vacuolar storage protein in bean seeds) results in an increased susceptibility to proteolytic cleavage and decreased stability of the protein in transgenic tobacco seed.[260] A general effect of glycosylation on protein stability is indicated by similar studies of other seed vacuolar proteins (e.g., PHA and barley lectin).[82,251] The role of high-mannose glycans in the folding and assembly of soybean lectin was examined by determining the ability of different oligosaccharides to interfere with the reconstitution of the lectin from denatured subunit polypeptides.[261] The combined use of spectroscopy and size analysis by gel filtration revealed that both folding and assembly of denatured subunits were completely prevented in the presence of $Man_9GlcNAc_2Asn$ (M9-Asn). In contrast, the oligosaccharide GM9-Asn ($Glc_{1-3}Man_9GlcNAc_2Asn$) interfered with polypeptide assembly. These results suggest that the branch Man α1-2 Man α1-2 Man linked to the 3 position of the β-mannosyl residue of the high-mannose chains (Figure 13) functions in the folding of the subunit polypeptides, whereas assembly of folded subunits is associated with other branches.[261]

Glycosylation of proteins destined for secretion or the cell wall is very important in some plant species (e.g., carrot). The correctly glycosylated 52- to 54-kDa secreted protein is thought to play a crucial role in carrot somatic embryogenesis.[262] In tunicamycin-treated carrot cells, nonglycosylated cell-wall β-fructosidase is degraded in the endomembrane system immediately after synthesis.[259] The glycan heterogeneity characteristic of extracellular plant proteins may be important for the interaction of those proteins with the various components of the cell wall and cell surface (extracellular matrix).[239] Transport efficiency may also be affected by glycosylation. In animal cells, transport of the vesicular stomatitis virus G protein to the cell surface is completely abolished when the protein's glycosylation sites are eliminated by site-directed mutagenesis. Conversely, the creation of additional glycosylation sites in the protein (at certain positions) promotes transport, as a consequence of having a positive effect on protein folding.[60]

As discussed in the next section, newly synthesized proteins often associate with a variety of ER-resident molecular chaperones and folding enzymes to ensure that transport out of the ER lumen is limited to properly folded and assembled proteins. In animal cells, newly synthesized influenza virus hemagglutinin (HA) and vesicular stomatitis virus G protein associate transiently during their folding with calnexin, a membrane-bound ER chaperone. This association is dependent on the composition of the glycoprotein's N-linked glycans.[263] For example, inhibitors of N-linked glycosylation and of the enzymes involved in glucose trimming (glucosidases I and II) prevent an association of the nascent proteins with calnexin, whereas inhibitors of mannose trimming do not. Proteins with monoglucosylated glycans are the most likely binding species. Thus, a model has emerged that envisions the ER as containing a unique folding and quality control machinery in which calnexin acts as one chaperone that binds proteins with partially trimmed carbohydrate chains. Glucose trimming may provide a mechanism by which resident ER proteins can monitor the folding and maturation status of newly synthesized glycoproteins. The detailed configuration of the N-linked oligosaccharides may reflect the degree of folding, the state of oligomerization, duration in the ER, and so on. ER degradation may also be connected to trimming and calnexin association.[263] For example, the conditions that prevent glycoproteins from binding to calnexin also increase the degradation rate of some proteins.[264] While intimately involved in folding and oligomer assembly of glycoproteins, the calnexin system may have evolved mainly to ensure quality control. Although all newly synthesized glycoproteins so far tested bind transiently to calnexin, only a subgroup show folding and secretion defects in the presence of glucosidase inhibitors that inhibit this interaction.[265] When prevented from binding to calnexin then, many glycoproteins find alternative ways of folding and assembly in the ER lumen, the latter made possible by high concentrations of other ER-resident chaperones and redox enzymes.[263]

2. Folding and Oligomer Assembly

Among the numerous modifications that proteins of the secretory pathway undergo, one of the most important is the acquisition of a functional, three-dimensional structure and the assembly of polypeptide subunits into oligomers. With few exceptions, these processes take place in the lumen of the ER and in large part will determine a protein's stability and subsequent efficient transport (reviewed in References 4, 17, 59, 60, and 73). Many plant vacuolar proteins (e.g., storage proteins) are oligomers (commonly dimers, trimers, tetramers, or hexamers), most of which undergo complete oligomerization in the ER.[125,266] Most lectins and several enzymes destined for the vacuole or the cell surface are active in the ER, which is indicative that they have attained a functional three-dimensional conformation and are properly assembled.[49,245,267,268]

As mentioned in the previous section, transport of proteins out of the ER is subject to various rules of ER quality control and is often the rate-limiting step in transport along the secretory pathway.[16] Correct folding and assembly of proteins is necessary for their efficient exit from the ER and subsequent transport.[59] Thus, "sorting" of proteins at this step appears to be conformation specific, and failure to acquire the correct conformation can result in ER retention and/or degradation (see later discussion). The efficiency of protein folding *in vivo* is due, in part, to several resident proteins of the ER that play a role in assisting in both the folding and oligomer assembly of nascent proteins. Folding of most proteins likely begins before synthesis/translocation of the entire protein has been completed, as soon as a protein domain emerges into the ER lumen (reviewed in Reference 4). In fact, it appears that a nascent polypeptide chain is accosted on the luminal side of the ER membrane by a "welcoming" committee of enzymes and factors that facilitate and accelerate folding in several ways.[59,60,73,123,269–271] Perhaps the best characterized of these ER "helper" proteins (termed "molecular chaperones") is BiP (in mammalian cells also known as the glucose-regulated protein, GRP78).[131] BiP is related to the cytosolic heat-shock proteins (of the Hsp70 family), but is a soluble protein that is targeted to the ER by a cleavable signal peptide; a carboxy-terminal (H/K) DEL sequence mediates its retention.[70,131] Although the main function of BiP is probably to promote protein assembly, it may also serve to prevent export of proteins from the ER[59] (see later discussion). The existence of an ER-localized BiP has been demonstrated recently in tomato, tobacco, bean (*Phaseolus vulgaris*), spinach, and in the endosperm of maize and the aleurone layer of barley.[17,59,135,136,139,272–274] Although the plant and mammalian BiPs share sequence homology with the members of the 70-kDa heat-shock protein family, they are not themselves heat inducible.[4,131,139,272]

In addition to BiP, several other ER-resident proteins potentially involved in facilitating folding and assembly of nascent proteins have been identified recently in plants. One such protein is PDI (see later discussion). Others are calnexin and endoplasmin; the latter is an abundant ER resident also referred to as glucose-regulated protein 94.[275–277] Putative homologs of the mammalian endoplasmin have been identified in bean and tobacco.[141,272] The tobacco protein can be detected immunologically within the ER, and internal microsequence data reveals considerable sequence conservation to the mammalian endoplasmin.[4] Barley and periwinkle cDNA clones encoding 94-kDa proteins are identical in sequence to the tobacco counterpart within the region of the microsequence, and exhibit 78% identity at the amino acid level; both contain a C-terminal ER-retention signal, KDEL. As mentioned in the previous section, calnexin is another type of molecular chaperone that interacts with many nascent membrane and soluble proteins of the secretory pathway (reviewed in Reference 278). It is unrelated to BiP and endoplasmin and is further distinguished in that it is an integral membrane protein. A cDNA clone encoding a protein related to calnexin has been isolated from *A. thaliana*.[279] The plant calnexin cDNA encodes a protein of ~60 kDa, and shows an overall sequence identity of 48% to dog calnexin. The proteins from both organisms are ER associated and contain a large luminal domain followed by a single potential membrane-spanning domain near the C-terminus; a small C-terminal domain (that can be serine phosphorylated *in vitro*) is exposed to the cytoplasm (see Reference 279 and references therein). In pea plants, a calnexin-like protein is detected in microsomal fractions of different vegetative tissues (e.g., leaves, shoots, stems) and at different developmental stages (e.g., etiolated buds and light-grown leaves). Its constitutive expression is indicative of a fundamental function within many types of plant cells. A search is now underway to carry out structure-function studies focusing on the conserved sequences of the plant calnexin.[279]

As mentioned previously, the main function of BiP (and some of the other molecular chaperones) is probably to promote protein assembly; it also may serve to prevent export of misfolded proteins from the ER.[59] Synthesis of BiP is induced when abnormal proteins accumulate in the ER,[280,281] and it preferentially associates with such proteins until they either fold correctly or are degraded. Thus, by specifically retaining abnormally folded and incompletely assembled proteins, BiP contributes to the selectivity of transport.[59] Abnormal products retained in the ER by BiP include mutant and misfolded forms of proteins (e.g., influenza HA),[257] chimeric proteins, and some unglycosylated forms of proteins (e.g., invertase).[282–284] In an *in vitro* translation/translocation system, it binds to unoxidized, but not to mature, disulfide-bonded prolactin.[282] A role in promoting protein folding per se is suggested perhaps by helping to prevent the aggregation of folding intermediates. More specifically, proteins such as BiP may act as reversible detergents, binding to hydrophobic surfaces, but intermittently utilizing ATP to change their conformation to a nonbinding state.[285] In this manner, unfolded proteins would be maintained in solution without sequestering them permanently in a nonfunctional complex; the proteins could thus avoid aggregation or precipitation but still be able to achieve their final tertiary and quaternary structures.[59]

In addition to the ER, other organelles of the eukaryotic cell are supplied with their own set of "helper proteins." Cytosolic, mitochondrial, and chloroplast proteins belonging to the Hsp70 and Hsp60 families may function in a manner similar to BiP; like BiP, they are also ATPases that are characterized by ATP-independent binding of substrate and subsequent release in a step that is dependent on ATP hydrolysis (reviewed in References 4 and 278). Chaperones of the Hsp60 and Hsp70 families cooperate with each other, as well as with other chaperones, in the binding and release of unfolded proteins. During biosynthesis of the vesicular stomatitis virus G glycoprotein and the class I heavy chain IgG, there are interactions with both calnexin and BiP.[263,286] Thus, cooperation between chaperones may be a key factor in facilitating the folding of nascent proteins within the ER.[278] As intimated, secretory proteins may interact with certain molecular chaperones such as BiP and calnexin before they achieve their mature, correctly assembled, state.[282] In mammalian cells, BiP binds transiently in the ER to a portion of IgG heavy chains until assembly with the appropriate light chain occurs.[287,288] If no light chains are available, then the heavy chains remain associated with BiP until they are degraded. In a temperature-sensitive BiP mutant of yeast, BiP is essential for viability; import of proteins into the ER ceases within minutes of warming to the permissive temperature.[289] Thus, BiP interacts with a variety of nascent proteins and (in yeast cells, at least) may be required for some of them to complete their translocation into the ER,[59] a process aided by additional proteins (e.g., SEC61) that appear to be components of the translocon, a delicate structure closely apposed to polypeptides that are moving through the membrane (see earlier discussion).[93,113,115]

The ability of the tobacco BiP homolog to correct a temperature-sensitive BiP (*kar2*) defect in *S. cerevisiae*[139] provides strong evidence that the functional role of plant BiP in the ER is similar to that of the yeast and mammalian BiPs. The level of tobacco BiP is elevated in tissues of germinating seedlings and in organs containing specialized secretory tissues such as the anthers and stamens, in which the constituent cells likely have a large flux of protein through the secretory pathway.[139] ER isolated from aleurone layer cells of the barley grain contains a BiP cognate whose synthesis is upregulated by GA_3 and down-regulated by ABA.[273] In maize endosperm, the abundance of BiP and its mRNA increases dramatically following tunicamycin treatment (as occurs in mammalian cells). The antibiotic increases the amount of misfolded protein in the ER as a consequence of its inhibitory effect on protein glycosylation; thus, the requirement for BiP is increased. The association of BiP with polypeptides synthesized in the presence of tunicamycin (e.g., the bean seed storage protein phaseolin) can be reversed *in vitro* by the addition of ATP.[272,290] Presumably, the permanent misfolding of unglycosylated polypeptides causes continuous binding, release, and rebinding to BiP, lowering the concentration of unbound chaperone in the ER.[4] A similar increase in BiP and its mRNA occurs in mammalian and yeast cells in response to tunicamycin. Interestingly, yeast cells can monitor the concentration of free BiP in the ER and adjust the level of transcription of the BiP gene accordingly,[291] the latter mediated via a *cis*-acting element of the promoter (the 'unfolded protein response element'). This domain is similar in sequence to those located in the upstream regions of the mammalian BiP and *grp94* genes

accumulates in transgenic tobacco seeds to a much lower amount than its unmodified counterpart. However, the "hi-met" protein is transport competent and appears to be degraded in the vacuoles (protein bodies) and not in the ER.[312] In contrast, trimerization of phaseolin subunits is required for transport of phaseolin out of the ER in *Xenopus* oocytes;[229] monomeric phaseolin is retained in a pre-Golgi compartment until trimers are formed. A mutant of phaseolin generated by deleting a domain required for trimer formation remains as a monomer in *Xenopus* oocytes and is unable to reach the Golgi complex. Transient expression of the wild type and mutant phaseolin polypeptides in tobacco leaf protoplasts[290] indicate a similar recognition of assembly status in plant cells. The phaseolin mutant occurs in ATP-dependent association with BiP, strongly suggesting an ER location; there, the mutant polypeptides are rapidly degraded. Thus, the general features of a quality control system within the ER are conserved between plant and animal kingdoms. The extent of conservation of specific features will await greater understanding of the processes of ER retention, protein folding, and assembly and degradation of unfolded or defective proteins.[4]

3. Formation of Disulfide Bonds

Many proteins transported along the secretory pathway (e.g., seed storage proteins and extracellular proteins) have disulfide bonds that stabilize their tertiary and quaternary structures. The formation of these bonds is not random but is rapidly catalyzed in nascent chains by PDI (Figure 15) (reviewed in References 269 and 313). This enzyme interacts with unfolded proteins in the ER and catalyzes thiol oxidation and disulfide exchange reactions.[129] Depending on the nature of the polypeptide substrate and the imposed redox potential, PDI promotes disulfide formation, isomerization, or reduction. Mammalian PDI is a dimer of identical subunits, each of which contains two nearly identical putative active-site regions bearing close resemblance to the active site of the thioredoxins.[314] In mammalian cells, PDI has several distinct roles. Besides existing as a free monomer, it is also an essential subunit (the β-subunit) of prolyl-4-hydroxylase (an enzyme that catalyzes the modification of prolyl residues); PDI also binds to the Asn-X-Ser/Thr acceptor sequence for N-linked glycosylation and is an important component of oligosaccharide transferase, an enzyme that is essential for glycan transfer (i.e., as the glycosylation-site binding protein).[130] However, involvement of this enzyme during N-linked glycosylation in the ER is not demonstrated, and depletion of PDI from microsomes does not affect their capacity to elaborate oligosaccharides onto nascent polypeptides.[315] PDI has also been identified as a component of the microsomal triglyceride transfer protein complex.[316] In addition, the vertebrate enzyme shows substantial similarity in its amino acid sequence (including the two active sites) with rat phosphatidylinositol-specific phospholipase C (PI-PLC),[317] and contains two regions with sequence similarity to hormone-binding domains of the human estrogen receptor.[318] Mammalian PDI can be crosslinked to nascent immunoglobulin chains *in vivo*,[319] which may be indicative of a role in correct protein folding. However, PDI does not determine the polypeptide folding pathway, but rather facilitates formation of the correct set of disulfide bonds by promoting rapid reshuffling of incorrect disulfide pairings[269] (Figure 15). Also, in the presence of PDI, formation of the correct disulfide bonds is possible at higher oxidizing conditions compared with the spontaneous reaction.[320]

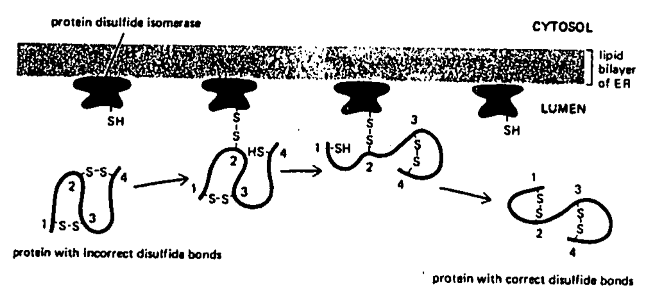

FIGURE 15. Action of protein disulfide isomerase. In the ER lumen, the enzyme protein disulfide isomerase acts repetitively to cleave intrachain S-S bonds until their arrangement has achieved the lowest overall free energy, at which point the protein is folded correctly. In this way, the enzyme facilitates the folding of the newly synthesized proteins that enter the ER. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 2nd ed., Garland Publishing, New York, 1989. With permission from Garland Publishing.)

PDI has been detected in wheat, alfalfa, soybean, and tobacco, and some of the properties of these plant enzymes have been determined.[138,321-323] The wheat enzymes (from endosperm and aleurone layer cells) have molecular masses of ~130 to 150 kDa on gel filtration and a monomeric molecular mass of 57 to 60 kDa, suggesting that the native enzyme exists as a dimer.[322,323] The deduced amino acid sequence of alfalfa PDI contains the two thioredoxin-like active sites characteristic of vertebrate and yeast PDIs[324] and a C-terminal ER retention signal, KDEL.[128,138] Recently, immunogold labeling has localized PDI to the ER in soybean root nodules.[321] Whether the enzyme plays multiple roles in plant cells remains to be determined, although its importance for correct folding and disulfide bond formation has been established. All forms of PDI are soluble, or only loosely associated with the ER membrane, and are released by incubation at high pH. PDI-depleted microsomes can still import γ-gliadin (a nonglycosylated wheat storage protein), but the protein cannot achieve its correct disulfide-bonded state; reconstitution of microsomes in the presence of purified PDI restores this function.[315] Synthesis of the mRNA for alfalfa PDI is induced by tunicamycin, as is BiP mRNA; however, the protein induced by this treatment has a slightly lower molecular mass than in the absence of the drug.[138] The amount of PDI increases during seed development, reaching a maximum at 17 and 40 d of development in soybean seed and wheat endosperm, respectively.[129,321] In wheat grain, this corresponds to the period of endosperm development at which the rate of synthesis of disulfide-bonded storage proteins is maximal. PDI is also detected following germination and appears to be an indicator of seed viability. For example, PDI activity in microsome-enriched fractions from aleurone layers of normally germinating seeds is significantly higher than in their abnormally germinating counterparts and becomes more diminished in the latter as germination proceeds.[323]

In mammalian cells, ER proteins other than PDI also contain domains with homology to thioredoxin (e.g., ERp61 and ERp72, which are induced at the onset of immunoglobulin secretion in murine B cells).[144] In fact, it appears that the ER houses an extended range of enzymes that may use thioredoxin-like domains containing dithiol/disulfide active sites to carry out various functions in the co- and posttranslational modification of secretory proteins. It remains to be determined whether these proteins have additional roles in protein assembly that do not involve redox activity and whether they are residents of other compartments of the cell in addition to the ER.[269]

4. Amino Acid Modifications: Hydroxylation and Isoprenylation

Proteins that are secreted from plant cells such as extensins and other HRGPs of the cell wall[28] may also undergo modification to specific amino acid residues *en route* to the cell surface. For example, the biosynthesis of these proteins involves the hydroxylation of prolyl residues, followed by the glycosylation of many of the hydroxyprolyl residues.[325] These reactions are

carried out by 4-prolyl hydroxylase, an ER-associated enzyme and a glycosyl transferase that is associated with the Golgi complex.[212,326] It is not yet known whether the interesting protein homologies observed between 4-prolyl hydroxylase, PDI, and glycosylation site-binding protein of mammalian cells[130] are also present in plant proteins.[17]

The extensive posttranslational modifications to HRGPs (including hydroxylation, glycosylation, and crosslinking) are of importance to the role of these proteins in cell wall self-assembly and cell extension. Hydroxylation of proline residues may depend on multiple sequence-specific prolyl hydroxylases, rather than on a single conformation-dependent enzyme (reviewed in Reference 327). Furthermore, there are rules governing this modification; for example, Lys-Pro, Tyr-Pro, and Phe-Pro are not hydroxylated, whereas Pro-Val is consistently modified.

As mentioned previously, some proteins of the secretory pathway undergo isoprenylation, a modification that ultimately plays a role in plant growth, signal transduction, and membrane biogenesis (e.g., intracellular trafficking of membrane vesicles). Here, proteins are linked through a cysteinyl thioester bond to either a farnesyl or a geranylgeranyl moiety (reviewed in Reference 328). For some proteins (e.g., the small ras-like GTP-binding proteins), this modification is required for their assembly into membranes (including those of the ER, Golgi complex, and vesicles) and, hence, for their biological activity. In suspension-cultured cells of tobacco, there are at least two distinct prenyl:protein transferases. One utilizes farnesyl pyrophosphate and preferentially modifies a substrate protein with a CAIM carboxy-terminus (farnesyl:protein transferase). The other utilizes geranylgeranyl pyrophosphate and preferentially modifies a substrate protein that has a carboxy-terminus with the sequence CAIL (geranylgeranyl:protein transferase type I).[329]

5. Proteolytic Processing

Proteins transported along the secretory pathway often undergo posttranslational proteolytic processing, including seed storage proteins, defense-related proteins (destined for secretion or vacuolar transport), and various vacuolar enzymes (e.g., α-mannosidase and thiol proteases). For seed storage proteins, this may occur during their transit to the vacuole (i.e., along the secretory pathway), but more commonly occurs upon reaching their final destination (i.e., within the vacuole).[330] In some cases, the polypeptide is simply cleaved into two or three smaller polypeptides, all of which remain together in the oligomer; in others, a domain is lost (e.g., from the amino-terminus, carboxy-terminus, or middle of the polypeptide). The degree of processing is also variable; it may be complete or only partial, with some polypeptides remaining unprocessed (Table 6).[330] In the vacuole/protein body of the developing soybean seed, glycinin (a legumin-type storage protein) occurs as a 12S hexamer in which each of the six subunits is composed of an acidic and a basic polypeptide joined by a single disulfide bond.[331] Proglycinin subunits are assembled into 9S trimers in the ER, and, following their intracellular transport through the secretory system, arrive at the vacuole in that form. Within the protein body/vacuole, a specific cleavage occurs, yielding the acidic and basic polypeptides and the trimers assemble into hexamers[125,266] (Figure 16).[332] Assembly of monomers into trimers and then into hexamers occurs *in vitro*; this system has been used to evaluate the effects of protein modification on oligomer formation.[333] Interestingly, the assembly of glycinin trimers into hexamers requires the proteolytic cleavage of proglycinin into its basic and acidic subunits. For this reason, cleavage is considered a potential regulatory step in the pathway leading to glycinin deposition. The processing of glycinin is effected by a one-point cleavage that occurs at the carboxyl side of the asparaginyl residue located at the junction of the subunits, the modification being carried out by a cysteine endoprotease present in the vacuoles/protein bodies of soybean cotyledons.[334–336] Proteolysis is largely attributable to the conformational accessibility of the enzyme to the asparaginyl residue. Putative vacuolar processing enzymes are also involved in the cleavage of other classes of storage proteins, including the 2S albumins of *Arabidopisis*, *Brassica*, and other

TABLE 6
Types of Proteolytic Processing of Vacuolar Proteins

No proteolytic processing[a]	N-terminal domain lost
Phytohemagglutin	Napin
Soybean agglutinin	Sulfur-rich protein of brazil nut
β Subunit of soybean β-conglycinin	Tomato proteinase inhibitor I
Tomato proteinase inhibitor II	Potato proteinase inhibitor I
Pea vicilin	Sweet potato sporamin
Phaseolin	α and α′ subunits of soybean β-conglycinin
Patatin	
C-terminal domain lost	**Internal cleavage with or without loss of a domain**
Soybean glycinin	12S globulins
Wheat germ agglutinin	Sulfur-rich protein of brazil nut
Barley lectin	Napin
	Castor bean ricin
Cleavage and religation	Castor bean *Ricinus communis* agglutinin
Concanavalin A	Pea lectin
	Pea vicilin

seeds;[337] the thiol protease of barley aleurone layer cells (aleurain) is also processed by a specific endoprotease located within the vacuole.[338]

Of all seed storage proteins studied, the 2S albumins[339] undergo some of the most extensive posttranslational processing. Maturation is a multistep process that follows cleavage of the signal peptide, and involves the removal of three peptides: an amino-terminal, an internal, and a carboxy-terminal fragment.[340,341] In the mature protein, subunits of 9 and 4 kDa remain that are linked by disulfide bonds. Posttranslational cleavages occur on the C-terminal sides of asparagine residues 35 and 74, which are conserved among the 2S albumin precursors in seeds of different plant species.[342] The two Asn residues are located in the hydrophilic regions of the precursor, suggesting the vacuolar processing enzyme can recognize exposed Asn residues on the surface of the protein and effect cleavage on the C-terminal side of these residues.[342]

As noted earlier, certain defense-related proteins, including chitinases, endo β-glucanases, and α-amylase inhibitors also undergo proteolytic processing. For the α-amylase inhibitor of bean seeds, cleavage upon arrival at the vacuole/protein body serves to activate the protein, possibly by removing a conformational constraint on the precursor.[343]

Some of the proteases involved in the postgerminative mobilization of seed storage proteins have been identified (see References 344 through 352); however, their transport to the vacuole has not been characterized.

E. Transport of Proteins Through the ER and Golgi Complex

All of the transport steps from the ER to the Golgi complex and transport through the Golgi itself are common to most proteins of the biosynthetic/secretory pathway and occur via a signal-independent (bulk-flow) mechanism (see earlier discussion). Proteins destined for locations beyond the ER are transported in small membranous vesicles that bud from the smooth regions of the ER membrane. These so-called 'transition' vesicles are directed to the Golgi apparatus which is composed of flattened, membrane-enclosed saccules. In animal cells, the Golgi apparatus comprises three distinct compartments, each con-

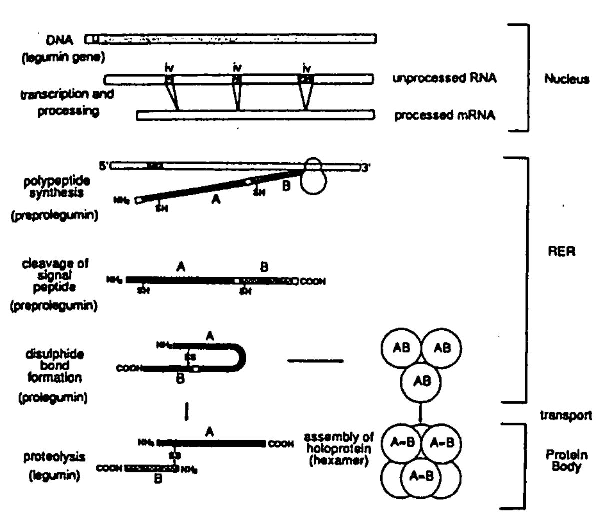

FIGURE 16. A representation of the synthesis and processing of the legumin (glycinin) in soybean cotyledons. Following transcription, the mRNA encoding glycinin is transported from the nucleus to the rough endoplasmic reticulum (RER), where it is translated. The mRNAs for the acidic (A) and basic (B) subunits are joined by codons for a 4-amino-acid linker sequence on the primary translation product (preprolegumin). The mRNA also contains a code for the signal peptide at the amino-terminal end and a pentapeptide at the carboxy-terminal end. The primary product (prolegumin) is processed to yield the A and B subunits joined by the linker sequence and disulfide bonds (S-S); the signal peptide and the pentapeptide are cleaved off. In the final step of processing the mature protein is formed as the linker sequence is removed, and the acidic and basic subunits are joined only by the disulfide bonding. The mature acidic subunit contains 278 amino acids (approximately 40 kDa) and the basic subunit 180 amino acids (approximately 20 kDa). Assembly of the subunits within the protein bodies yields the mature hexameric legumin holoprotein. Based on Krochko and Bewley.[332] Reprinted with permission of Longman Group UK (Gale Research, Inc.). See also Dickinson et al.[286] for details and Bednarek and Raikhel[83] for a general review. taining a characteristic array of protein-modifying enzymes, the *cis*, *medial*, and *trans* cisternae, plus the tubular TGN.[353] Movement through the Golgi compartments is mediated by the budding and fusion of transport vesicles. Much of the present work in animal cells and yeast is focused upon the mechanisms of protein movement through the Golgi stacks and how proteins are sorted according to destination, then packaged for delivery.[15] In both systems, signal-dependent sorting of proteins away from bulk flow (i.e., to the lysosome/vacuole or to secretory vesicles) occurs in the TGN, a complex tubular reticulum in which proteins are segregated into different transport vesicles to be dispatched to their final destinations.[56,354] Thus, in this compartment protein traffic signals are recognized by specific receptors that sort proteins according to their proper destination. For example, soluble lysosomal enzymes are diverted to lysosomes by a mechanism involving a protein sorting signal (a modification of a N-linked carbohydrate chain) and a membrane-bound receptor that recognizes the specific carbohydrate modification (reviewed in Reference 85). Likewise, within cells involved in regulated secretion, selected proteins undergo sorting and dense packing into special vesicles in the TGN.[355]

1. Vesicles Involved in Transport

In mammalian cells, the vesicles that transport proteins from the TGN to other compartments (via sorting-dependent mechanisms) are covered with a protein coat consisting of clathrin[356] and a subset of characteristic polypeptides.[357] Small clathrin-coated vesicles function in both receptor-mediated endocytosis as well as in the receptor-mediated transport of proteins to the lysosome (reviewed in References 16 and 358 through 360). The endocytic and lysosomal transport pathways meet in the TGN. The participation of mannose-6-phosphate receptors in both transport pathways is mediated by independent domains on the receptor molecule.[361–363] A cytoplasmic tail domain on the mannose-6-phosphate receptor directs its clustering in Golgi-localized clathrin-coated buds, mediated by a number of 'adaptor' molecules. From these buds, vesicles form, carrying the receptor and its ligand for transport to lysosomes and eventual recycling of the receptor to the Golgi complex. A second domain directs entry of the receptor into clathrin-coated pits on the plasma membrane mediated by a different set of adaptor molecules. The two domains on the receptor protein function independently and do not compete for the same set of adaptor molecules.[362,363]

As intimated above, coated pits concentrate selected vesicle cargo, usually transmembrane receptors bound to a soluble ligand, while excluding resident membrane proteins. The cytoplasmic

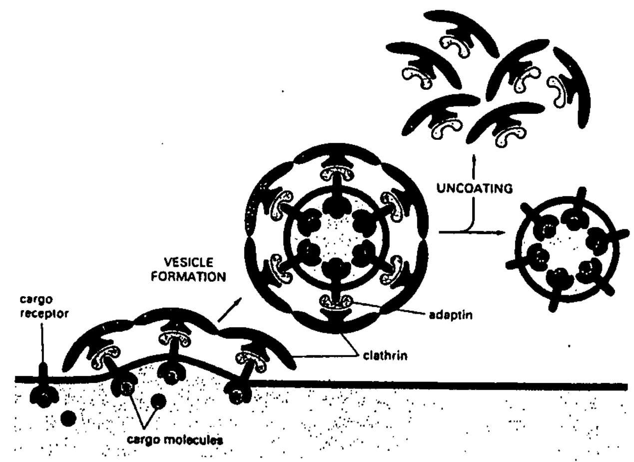

FIGURE 17. Selective transport mediated by clathrin-coated vesicles. The adaptins bind both clathrin triskelions and cargo receptors. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 3rd ed., Garland Publishing, New York, 1994. With permission from Garland Publishing.)

face of the coated pit is composed of a layer of clathrin-associated proteins (adaptins) bound to the membrane, surrounded by an attached lattice of clathrin subunits thought to be assembled by the recruitment of soluble forms of clathrin and adaptins to the membrane (reviewed in Reference 364). Coated pits progress to form vesicles; once released from their membrane attachment, mature coated vesicles are rapidly uncoated, releasing clathrin and adaptins for another round of coated pit and vesicle formation (Figure 17). The uncoated vesicle is now a fusion-competent vesicular intermediate. An outstanding question is whether clathrin is involved in the export of constitutively secreted proteins and normal membrane proteins. One view is that the contribution of clathrin to intracellular traffic is quantitative rather than absolute; clathrin assembly concentrates and sorts receptors, facilitating their transport from one membrane to another.[359] It performs this function in both the import and export pathway, enhancing transport provided by bulk flow in either direction. Localized control of clathrin assembly through diverse molecular signals from receptors and coated-pit components allows its universal function to be applied to specific intracellular targeting.

The major structural component of the clathrin-coated vesicle is the clathrin triskelion, a three-legged structure comprised of three clathrin heavy chains (180 kDa) and three clathrin light chains (30 to 40 kDa), each bound to a heavy chain near the vertex of the triskelion.[365,366] Clathrin heavy chains may play a structural role in vesicle formation, effecting a change in membrane shape required to produce a curved vesicle.[367] The clathrin light chains, on the other hand, likely play a regulatory role in vesicle consumption by regulating the equilibrium between clathrin coat assembly and disassembly (reviewed in References 364 and 368). For example, disassembly of the clathrin lattice and release from the vesicle surface requires clathrin light chain, and is stimulated by the enzymatic action of Hsc70 (uncoating ATPase), a member of the heat-shock protein family.[369]

The adaptins of coated pits and vesicles are thought to mediate clathrin binding to membranes and play a role in the selection of vesicle cargo.[370,371] Two major adaptin complexes designated AP-1 and AP-2 (AP: assembly or adaptor protein) have been characterized biochemically and localized; AP-2 is associated with clathrin on the plasma membrane,[357] whereas AP-1 is found exclusively in association with clathrin in the TGN.[372] These adaptin complexes are thought to link the clathrin lattice with the membrane by binding both to clathrin and to transmembrane proteins in the coated vesicle membrane.[373] Their position within the 20 nm space between the vesicle surface and clathrin lattice is consistent with this proposed role; likewise, adaptin complexes are able to bind *in vitro* to the cytoplasmic domains of transmembrane receptors that are packaged into clathrin-coated vesicles.[359,363] For example, the cytoplasmic domain of the LDL (low-density lipoprotein) receptor binds the adaptin complex AP-2. Thus, they are likely to initially bind selected trafficking proteins in coated pits. When the lattice-coated membrane pinches off, all of these proteins are incorporated into free carrier vesicles.[374] Further elucidation of clathrin-adaptin interactions may come from reconstituted clathrin-coated vesicles and/or a genetic approach (e.g., in yeast).[364]

A vesicle with only a partial clathrin coat is involved in the dense packing of proteins secreted via a regulated (and sorting-dependent) mechanism.[375] In the formation of hormone-containing secretory granules, clathrin-coated pits and vesicles remove membrane from the site of a condensing secretory bud that will eventually pinch off from the TGN to form a secretory granule; the prohormone may be initially concentrated by a receptor-mediated process (reviewed in Reference 359). After granule acidification and prohormone processing, the receptors may be removed by clathrin, resulting in granule condensation to form the mature secretory granule.[56] This scheme again postulates that the role of clathrin and the associated adaptor complexes is to concentrate and sort receptors. It is now evident that the sorting of proteins destined for regulated secretion occurs upon exit from the TGN, where they are directed into vesicles distinct from those involved in the transport of secretory proteins of the constitutive pathway; this sorting also occurs faithfully in a cell-free system.[355] A small nonclathrin-coated vesicle is involved in bulk-flow transport; in contrast to the clathrin-coated vesicles, these carriers are found at all levels of the Golgi stack and contain protein at its prevailing (bulk) concentration in the parental Golgi cisternae (see later discussion).[376,377]

In the cells of higher plants, the structural relationships between the ER and Golgi apparatus and between intraorganellar transport pathways are much less clear.[17,29] However, there is evidence that some features of Golgi structure and vesicular transport are similar to those of animal cells. For example, ultrastructural analysis of the individual Golgi stacks in suspension-cultured sycamore cells identified three morphologically distinct cisternae.[235] In plant cells, physical connections between the *trans*-Golgi and the partially coated reticulum (an organelle consisting of tubular membranes bearing clathrin-like coats over parts of their cytoplasmic surface) are indicative that the latter resembles the TGN of animal cells.[378] Clathrin-coated vesicles are involved in endocytosis in plant cells;[358,379] they may also participate in the sorting-dependent transport of proteins to the plant cell vacuole. For example, precursors of vacuolar seed storage proteins and lectins are found in clathrin-coated vesicles isolated from developing pea cotyledons.[380–382]

Research on plant clathrin-coated vesicles has been impeded in large part by the difficulty of obtaining sufficient quantities of intact, pure, and undegraded vesicles with which to work.[2,383] The heavy and light chains of plant clathrin are 10 to 15 kDa larger than their animal counterparts (Figure 18).[384–386] Most of the adaptor polypeptides (as well as receptors) remain to be identified; however, there is now evidence for a β-type adaptin (i.e., a plant equivalent of the β-adaptin component of the complex AP-2 of mammalian cells).[387] A major 28-kDa polypeptide in clathrin-coated vesicle fractions of pea cotyledons, initially thought to be an adaptin, has now been identified as a contaminant (phytoferritin).[383] This latter study has underscored the limitations of using certain plant tissues as a source for clathrin-coated vesicle isolation (e.g., embryonic tissues such as cotyledons that store large amounts of ferritin and photosynthetic tissues in which postmicrosomal fractions are contaminated with the chloroplastic enzyme, ribulose bisphosphate carboxlase-oxygenase).

As mentioned previously, uncoating of clathrin-coated vesicles is a prerequisite to vesicle fusion with the target membrane. Recently, a cytosolic uncoating ATPase (an enzyme that dissociates clathrin from clathrin-coated vesicles in the presence of ATP) has been isolated from developing pea cotyledons using chromatography on ATP-agarose.[388] The properties of the plant enzyme are markedly similar to those of the uncoating ATPase of mammals and yeast. Thus, despite the dissimilarities in the molecular weights of the clathrin components of vesicles from their respective sources, uncoating appears to be achieved by a common mechanism.[388] Characterization of additional coat components of plant vesicles and sequence analysis of identified coat proteins will allow a more detailed investigation of the uncoating process; the mechanism of uncoating may be elucidated by uncoating experiments carried out *in vitro*, in which clathrin baskets lack specific coat components.[388]

2. Mechanisms of Vesicle Budding, Targeting, and Fusion: Cytosolic Factors, Receptors, and GTP-Binding Proteins

Insight into the mechanisms of vesicle budding, targeting, and fusion has come from the use of a variety of experimental approaches in both animal cells and yeast (reviewed in References 389 through 396). Semi-intact cells made permeable to macromolecules have been used to study ER to Golgi traffic.[397,398] In this system, there is efficient reconstitution of intracellular transport, provided ATP and a cytosolic fraction are added.[397] *In vitro* cell-free systems have been developed for yeast.[399] The secretory pathway in yeast has been partially defined by a series of temperature-sensitive mutant strains that are blocked at various stages in protein transport.[400–403] Such mutants were used to show that a number of complementation groups (and thus gene products) are required for the transport of secretory proteins from their site of synthesis to the cell surface; several are required for ER to Golgi transport alone. Additional gene products are necessary for intra-Golgi transport and for localization of yeast hydrolases to the lysosome-like vacuole. To inves-

tigate the function of these gene products, researchers are cloning these genes and characterizing the proteins they encode (reviewed in Reference 404). Secretory pathway mutants can be complemented by unique expression plasmids that contain segments of wild-type yeast DNA. Open reading frames are identified (by DNA sequence analysis), gene fusions to β-galactosidase are constructed and gene product-specific antibodies are generated.[16] In this manner, some of the proteins required specifically for ER to Golgi transport and for intra-Golgi transport have been identified and characterized (Figure 19).

Vesicular transport between cisternae of the Golgi stack has been demonstrated *in vitro*.[16] Transport of the vesicular stomatitis virus G protein from the *cis*- to the *medial*-compartments of the Golgi complex was shown to require a crude cytosolic fraction, ATP, and proteins isolated from the surface of the Golgi membranes (Figure 19).[405–407] A number of cytosolic factors (proteins) are involved in collecting proteins for vesicular transport, as well as mediating vesicle budding, transport, and fusion of the transport vesicle with the appropriate target organelle. Remarkably, the cytosol from yeast[408] and plants[409] can substitute for animal cell cytosolic extracts in promoting transport in the Golgi stack and in forming coated vesicles. This interchangeability is indicative that the transport machinery is extremely similar, even in detail, in all eukaryotes. More recently, techniques that were developed with rat liver were used to isolate a population of vesicles derived from ER in a cell-free system

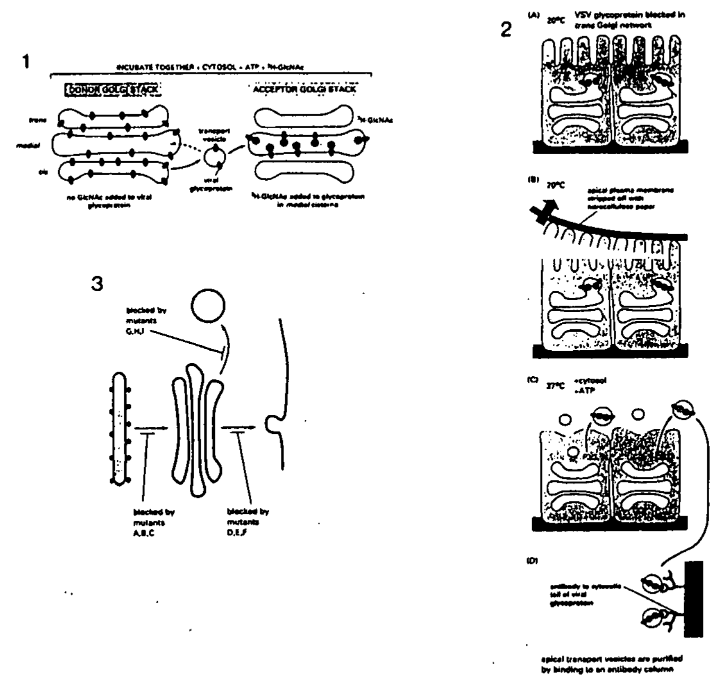

FIGURE 19. Approaches to the study of ER to Golgi and intra-Golgi transport in yeast and mammals. (1) Cell-free systems for studying the components and mechanism of vesicular transport. Reconstituted vesicular transport in cell-free systems was first achieved for the Golgi stack. When Golgi stacks are isolated from cells and incubated with cytosol and with ATP as a source of energy, transport vesicles bud from their rims and appear to transport proteins between cisternae. By following the progressive processing of the oligosaccharides on a glycoprotein as it moves from one Golgi compartment to the next, it is possible to follow the process of vesicular transport. To follow the transport, two distinct populations of Golgi stacks are incubated together. The "donor" population is isolated from mutant cells that lack the enzyme *N*-acetylglucosamine (GlcNAc) transferase I and that have been infected with a virus; because of the mutation, the major viral glycoprotein fails to be modified with GlcNAc in the Golgi apparatus of the mutant cells. The "acceptor" Golgi stacks are isolated from uninfected wild-type cells, and thus contain a good copy of GlcNAc transferase I, but lack the viral glycoprotein. In the mixture of Golgi stacks, the viral glycoprotein acquires GlcNAc, indicating that it must have been transported between the Golgi stacks — presumably by vesicles that bud from the *cis* compartment of the donor Golgi and fuse with the *medial* compartment of the acceptor Golgi. This transport-dependent glycosylation is monitored by measuring the transfer of ^{3}H-GlcNAc from UDP-^{3}H-GlcNAc to the viral glycoprotein. Transport occurs only when ATP and cytosol are added. By fractionating the cytosol, a number of specific cytosolic proteins have been identified that are required for the budding and fusion of transport vesicles. (2) Semi-intact cells. Vesicular transport can also be studied in cells whose plasma membrane has been permeabilized to allow small molecules and macromolecules to leave and enter the cell freely. Permeabilization is achieved by physical rupture or treatment with bacterial toxins that punch large holes in the plasma membrane. Such semi-intact cells are particularly useful for studying the transport from extended membrane systems that become extensively fragmented during conventional homogenization procedures, such as the ER and the *trans* Golgi network. Semi-intact cells have been used to isolate transport vesicles that mediate transport from the *trans*-Golgi network to the apical plasma membrane. (3) Genetic approaches for studying vesicular transport. Genetic studies of mutant yeast cells defective for secretion at high temperature have identified more than 25 genes that are involved in the secretory pathway. Many of the mutant genes encode temperature-sensitive proteins; these function normally at 25°C, but when the mutant cells are shifted to 35°C, some of them fail to transport proteins from the ER to the Golgi apparatus, others from one Golgi cisterna to another, and still others from the Golgi apparatus to the vacuole or to the plasma membrane. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J. D., *Molecular Biology of the Cell*, 3rd ed., Garland Publishing, New York, 1994. With permission from Garland Publishing.)

from plants that likely represent an intermediate compartment in membrane transfer between the ER and Golgi complex.[410]

The finding that proteins can transfer from one Golgi stack to another in a unidirectional fashion indicates that vesicles have a built-in targeting capacity; specifically, each type of vesicle has its own "address marker" that ensures that inappropriate transport does not occur. The target membrane must in turn have a complementary receptor that recognizes the address and allows docking of the vesicle.[15,16] This type of specificity is involved in transport from the ER to the Golgi and in intra-Golgi transport. Proteins from mammalian and yeast intra-Golgi transport vesicles and from Golgi membranes that appear to fulfill these functions have been characterized; however, the identity of some of these tags remains elusive. The working concept for such targeting is that during vesicle transit through the cytosol, the configuration of the polypeptides on the vesicle surface mediates vesicle docking and release of contents only when the correct membrane is encountered. Indeed, recent evidence indicates that vesicle docking involves the formation of a complex that includes proteins from the cytoplasm as well as proteins that are embedded in the vesicle and target membranes (reviewed in Reference 389). After reaching the TGN, proteins are sorted according to their correct final destination.

Vesicles responsible for intra-Golgi transport contain nonclathrin coat proteins (coatomer proteins or COPs), in addition to other associated proteins, including a small GTP-binding protein, ADP ribosylation factor (ARF). A cell-free assay developed for intra-Golgi transport in mammalian cells led to the identification and purification of a cytoplasmic protein needed for vesicles to fuse with their target membranes, called NSF (for NEM [*N*-ethylmaleimide]-sensitive fusion protein).[411] NSF was later found to be functionally interchangeable with SEC19 of yeast (reviewed in Reference 412). NSF carries two repeat motifs for an ATP-binding site, and ATP binding is critical for NSF-induced fusion.[393] Further work led to the identification of soluble NSF attachment proteins (SNAPs) — cytosolic proteins that associate with NSF to allow membrane association.[393] α-SNAP, one of the three SNAP proteins associated with NSF in mammalian cells, also has a yeast counterpart (i.e., SEC17).[412] The yeast protein SEC4, a ras-like GTP-binding protein, is crucial at a later stage in the secretory pathway, required for fusion with the cell membrane;[413] mammalian equivalents of the yeast SEC4 protein have also been identified (referred to as *rab*, for *ras* genes/proteins from rat brain; see later discussion). Thus, at least three protein families — NSF, SNAPs, and Rabs — are all cytoplasmic proteins that transiently associate with membranes.[389] Figure 20 presents a working model for vesicular transport between compartments of the Golgi complex that is envisioned as a GTP hydrolysis-driven cycle. ARF is myristylated at its amino-terminus that, in conjunction with its GTP-bound state, appears to regulate ARF association with membranes.[414,415] More specifically, ARF-GTP causes the binding of other coat components to the Golgi membranes, leading to the budding of coated vesicles. In this model, target membranes possess a GTPase activity that causes the hydrolysis of the ARF-bound GTP; thus, encounter with the target membrane destabilizes the coat (i.e., causes vesicle uncoating). This would recycle ARF and the coatomers to the cytosol and lead to the fusion of the uncoated vesicle with the target membrane.[393] A recently identified interaction between ARF and phospholipase D (PLD) activity links together the dynamics of coat formation/removal with phospholipid metabolism (reviewed in Reference 390). To add to this model, other groups of proteins important in the vesicle fusion process function as receptors for some of the soluble factors. These receptor proteins (referred to as SNAREs [SNAP receptors]) are thought to be permanently embedded in the membranes to act as markers and binding sites for the cytoplasmic proteins. These integral proteins, then, are of two varieties — those that are integrated into the vesicle membrane (v-SNARE) and those that reside in the target or acceptor membrane (t-SNARE).

An NSF-SNAP affinity matrix has been used to isolate putative SNAREs from bovine brain membrane extracts.[416] Purified recombinant NSF and SNAPs were mixed with detergent-solubilized bovine brain microsomes in the presence of ATPγS, and any complexes that formed were

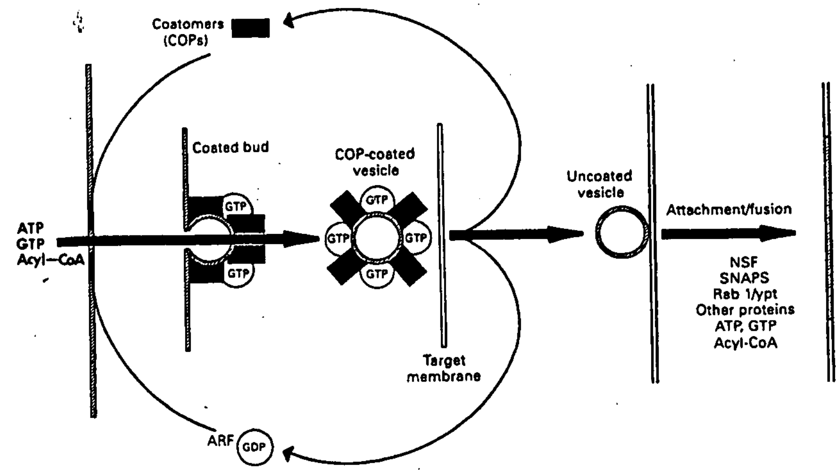

FIGURE 20. Working model for vesicular transport between Golgi compartments. The shaded membrane at left represents a portion of a Golgi cisternal membrane giving rise to a nonclathrin COP-coated vesicle that attaches to its target membrane (unshaded), the envelope of the next Golgi compartment in the secretory pathway. Specific targeting of the coated vesicle is proposed to be initiated by an unknown component in the recipient membranes. The vesicle is then uncoated and the general NSF-dependent fusion pathway is triggered, together with attachment of the now uncoated vesicle. Components of the coated vesicle include, but may not be limited to, coatomers (a complex of COPs, filled squares) and ADP-ribosylation factor (ARF), which can exist in both GDP- and GTP-bound forms (circles). The proposed cycle for coatomers and ARF has not been directly demonstrated. (From Rothman, J. E. and Orci, L., *Nature*, 355, 409, 1992. With permission from Nature and Macmillan Magazines Ltd.)

immunoisolated. Subsequently, the proteins that had bound in an ATP-dependent fashion were eluted using Mg-ATP. The eluate contained SNAPs and also a number of putative SNAREs, including syntaxins A and B and synaptobrevin (or VAMP); these proteins were previously identified as key membrane components of synaptic vesicles and the synaptic plasma membrane. Their localization was indicative of a role in synaptic-vesicle-plasma-membrane fusion. More direct evidence of a functional role in targeting/fusion came with the demonstration that NSF and SNAP interact to form a 20S complex. A model has now emerged in which the NSF-SNAP complex functions as a bridge between receptor proteins for SNAPs (SNAREs) in vesicular and target membranes of a fusion reaction.[395] The v-SNARE (the vesicle address tag) interacts with a target-membrane SNARE (t-SNARE), specifying targeting and leading to fusion by the SNARE interaction with SNAPs and NSF (Figure 21).[417] In brain synapses, syntaxins act as SNAREs in the target membranes (t-SNAREs) (i.e., the presynaptic cell membrane), whereas the synaptic vesicle protein synaptobrevin (VAMP) acts as the respective receptor in the vesicle membrane (v-SNARE).[416,418] Alternatively, the NSF-SNAP complex may act on a preexisting complex formed by syntaxin, synaptobrevin, and a third protein associated with the presynaptic membrane, SNAP-25 (synapse-associated protein).[418] Interestingly, the syntaxins (t-SNAREs) share sequence homology with several yeast proteins (SSO1, SED5, and PEP12) that are involved in membrane transport (Table 7).[412,419] The recent findings suggest a general model for vesicle targeting and fusion in

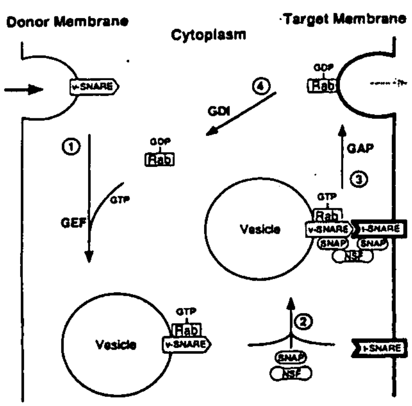

FIGURE 21. The SNARE hypothesis for vesicle fusion with the target membrane. According to this hypothesis, the v-SNARE protein located on the vesicles interacts with the t-SNARE found on the target membrane in the presence of NSF, SNAPs, small GTP-binding proteins, and other uncharacterized components. This interaction leads to the eventual fusion of the transport vesicles with the target membrane. In step 1, the small GTP-binding protein Rab is recruited to the vesicle in the presence of GEF and GTP. The recognition and interaction between v-SNARE and t-SNARE mediated by NSF and SNAP bring the vesicle to the target membrane (step 2). Hydrolysis of GTP by Rab with the help of GAP triggers the fusion of two distinct lipid bilayers (step 3). The GDP-bound Rab is released by GDI from the membrane to the cytosol for recycling (step 4). Fusion of the vesicle to the target membrane also releases the cargo of the vesicle for secretion into or outside of the membrane compartments (shaded arrow). The solid arrow indicates the formation of vesicles. (From Verma, D. P. S., Cheon, C.-I., and Hong, Z., *Plant Physiol.*, 106, 1, 1994. With permission from the American Society of Plant Physiologists.)

which the soluble protein NSF and the SNAPs (or their yeast counterparts SEC18 and SEC17) are common to fusion complexes throughout the cell, whereas the integral membrane proteins VAMP and syntaxin represent protein families whose members are located on different types of vesicles and take part in specific kinds of fusion.[389]

On a cautionary note, the model may be oversimplified because it was originally built on work on neurons in which release of neurotransmitter is regulated and not constitutive. However, the general SNAP-SNARE concept as a mechanism for directing fusion events in Golgi trafficking appears to operate in both constitutive and regulated secretion. It is likely that the regulated secretion mechanisms of neurons and other specialized secretory cells of animals use components of the general secretory machinery, but in addition, contain specialized components to make it regulated and able to respond to a specific stimulus. One

possible candidate for such a regulator is the vesicle protein synaptotagmin, which binds calcium and is not found in cells capable of only constitutive secretion (e.g., yeast).[420] The search is now on for other members of the v- and t-SNARE families — particularly the latter, because these proteins likely play very important roles in defining the fusion site on transport vesicles and in establishing and maintaining organelle integrity.[392]

Genetic and biochemical studies in yeast and mammalian cells have also led to significant advances in the identification of proteins that are involved in mediating ER to Golgi transport as well as elucidating the role of GTP-binding proteins as regulatory elements in the secretory pathway. By combining the power of yeast genetics with a permealized-cell transport system, Lian and Ferro-Novick[421] have implicated two vesicle integral membrane proteins, BOS1 and SEC22 (both v-SNAREs), that are required for fusion of vesicles involved in ER to Golgi transport with target Golgi membranes as well as the specificity of the membrane fusion event. Antibodies to BOS1 inhibit ER to Golgi transport *in vitro*, without affecting vesicle budding. The putative t-SNARE that interacts with BOS1 or SEC22 is SED5.[422] The *sed5* gene was isolated as a suppressor of the *erd2* mutation. As mentioned earlier, ERD2 is the KDEL receptor and is required for stability of the Golgi complex. When ERD2 is overexpressed, Golgi proteins appear to redistribute to the ER, and the Golgi complex disappears.[166] Depletion of the ERD2 protein, on the other hand, causes membranes to accumulate.[422] Evidence implicating SED5 as a t-SNARE that is required for consumption of transport vesicles is indicated by the finding that the temperature-sensitive *sed5* yeast mutant exhibits an accumulation of ER-derived vesicles; overexpression of SED5 also leads to vesicle accumulation, but these likely represent vesiculated Golgi membranes. Thus, SED5, like ERD2, may be required to maintain Golgi integrity.[392] Other membrane proteins implicated in ER-Golgi transport are BET1 and YPT1; the latter is a small Rab-type GTPase that is incorporated in ER-Golgi transport vesicles.[421] BET1 may represent a t-SNARE necessary for recycling vesicles in the retrograde pathway from the Golgi back to the ER.[392]

GTP-binding proteins have been implicated as key regulatory elements in the secretory pathway (reviewed in References 391 and 423 through 436). Notably, in the last decade, more than 30 different GTP-binding proteins of the Ras superfamily have been implicated in the regulation of membrane traffic at virtually every stage of the exocytic and endocytic pathways (Table 8).[391,417] In very general terms, GTP binding and hydrolysis controls switching between two different pro-

TABLE 8
Localization and Possible Function of Small GTP-Binding Proteins in Different Membrane Compartments

Protein	Localization	Possible function
Ras	Plasma membrane	Signal transduction
Ran	Nucleus	Nuclear protein import, DNA synthesis
Rac	?	Phagocytosis, membrane ruffling
Rho	Golgi, post-Golgi vesicles	Actin cytoskeleton
Arf	Golgi	Regulate budding from the ER and fusion at the Golgi stacks, endosomes, and nuclear vesicles
Sar	ER	Vesicular budding from the ER
Rab		
Rab1a	?	ER-Golgi transport
Rab1b	ER, Golgi	ER-*cis*-Golgi transport
Rab2	ER-Golgi intermediate compartment	ER-Golgi transport
Rab3a	Synaptic vesicles, chromaffin granules	Regulated exocytosis
Rab3b	Mainly in cytosol	Regulated exocytosis
Rab3c	Synaptic vesicles	Regulated exocytosis
Rab4	Early endosomes	Early endosome-plasma membrane recycling pathway
Rab5	Early endosomes, plasma membrane	Plasma membrane-early endosome transport, fusion of early endosomes
Rab6	TGN, post-Golgi transport vesicles	Budding from TGN
Rab7	Late endosomes	Transport in endocytic pathway
Rab8	Post-Golgi basolateral secretory vesicles	Golgi-plasma membrane transport
Rab9	Late endosomes, TGN	Late endosome-TGN transport
Rab11	TGN, secretory granules, synaptic vesicles	?
Rab12	Golgi	?
Rab13	Tight junction	Polarized transport, assembly of tight junction
Rab17	Basolateral plasma membrane	Transcellular transport
Rab22	Plasma membrane, endosomes	Endocytic pathway
Rab24	ER, *cis*-Golgi, late endosomes	Endocytic pathway

tein conformations; the switch serves to propagate and amplify regulatory signals. A subset of these proteins (G proteins) may mediate the vectorial transport of individual vesicles, specifying the direction of vesicular transport between appropriate cellular compartments.[404,423,427] The low molecular weight monomeric GTP-binding proteins fall into two subgroups. The first subgroup includes proteins of the ARF/Sar family that are involved in the formation of carrier vesicles from the donor organelle and in the preparation of the vesicles for fusion with the acceptor organelle (reviewed in Reference 394). The other family includes SEC4, YPT, and Rab proteins that control distinct vesicular transport events (Table 8).

A clear indication of the importance of GTPases is the inhibitory action of nonhydrolyzable GTP analogs such as GTPγS on, for example, intra-Golgi transport[428] and budding of secretory vesicles from the TGN.[355] GTPγS acts by locking the GTPase in an activated state.[429] For example, ARF is the cytosolic protein that confers sensitivity of a cell-free Golgi transport assay to GTPγS.[430] A ras-like GTP protein, Sar1, is required for ER to Golgi transport. Like ARF, the association of the Sar1 protein with ER membranes is GTP-dependent. A facilitatory role is played by a 70-kDa integral membrane glycoprotein (SEC12, a resident of the ER), which promotes the association of Sar1 with the ER and thereby promotes protein transport from the ER to the Golgi complex. SEC12 has been identified as a GDP/GTP exchange protein (see later discussion).[431] Another participant is SEC23, a GTPase-activating protein (GAP) specific for the Sar1 protein; in carrying out its role, a complex is formed with another protein required for vesicle budding, SEC24.[432] The model that emerges (Figure 22) then is a process in which Sar1, with the aid of SEC12, binds GTP, associates with the ER, and then (helped by SEC23/SEC24) hydrolyzes GTP to catalyze the formation of a transport vesicle. Although not shown in Figure 22, coatomers are not only important in intra-Golgi transport, but are also required for ER to Golgi transport (see Reference 394 and references therein).

As noted above, the second subgroup of GTP-binding proteins — SEC4, YPT, and Rab proteins — control distinct vesicular transport events (Table 8). Genetic evidence indicates that different members of the SEC4/YPT/Rab protein family have unique cellular functions and, for the most part, cannot replace each other. For example, overexpression of the *ypt1* gene will not compensate for deletion of the *sec4* gene and vice versa. The yeast *ypt1* gene encodes a ras-like protein that binds and hydrolyzes GTP; this protein resides in the Golgi complex and in ER-Golgi carrier vesicles and is required for transport from the ER to and through the Golgi complex.[421,426,433] For example, the yeast mutant strain *ypt1* accumulates vesicles and antibodies to the YPT1 protein block ER to Golgi transport *in vitro*. Interestingly, mammalian homologs of the YPT1 protein,[434–436] Rab1a and Rab1b, are 75 and 66% identical to the YPT1 protein, respectively.[436] Like YPT1 of yeast, Rab1 is essential for both ER to Golgi and intra-Golgi transport in mammalian cells *in vivo* and *in vitro*.[437,438]

The protein SEC4 plays an essential role at late stages of the yeast secretory pathway. Most of the SEC4 protein is attached to the cytoplasmic faces of both post-Golgi secretory vesicles and the plasma membrane; the remainder is soluble in the cytoplasm.[439] This diversity in location suggests that proteins of the SEC4/YPT/Rab family may undergo a cycle of localization as they fulfill their functions.[391,425,426] Newly synthesized SEC4 rapidly associates with secretory vesicles that go on to fuse with the plasma membrane. The plasma membrane-bound pool can recycle onto a new round of vesicles as they accumulate in a secretory mutant blocked in exocytosis; this recycling

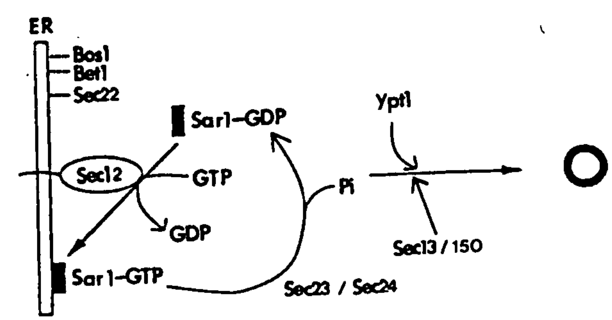

FIGURE 22. Some proteins involved in ER to Golgi transport in yeast. See text for details. ER-derived vesicles contain Sec22, Bos1, and Ypt1. (From Takizawa, P. A. and Malhotra, V., *Cell*, 75, 593, 1993. With permission from Cell Press.)

pathway may utilize a soluble intermediate. The SEC4 protein may act primarily on the vesicle's surface to transduce an intracellular signal needed to regulate transport between the Golgi complex and the plasma membrane.[439] Another particle (SEC8/SEC15) is found in the cytosol and is peripherally associated with the plasma membrane, but not with secretory vesicles. It may function as a downstream effector of the SEC4 protein, serving to direct the fusion of vesicles with the plasma membrane; there is indirect evidence of a weak association of SEC4 with this complex.[413]

In plants, virtually no functional studies of GTP-binding proteins have been undertaken due, in part, to the lack of *in vitro* model systems and the difficulty of screening for mutants that are defective in the endomembrane transport system.[4] However, the recent identification of cDNA clones encoding proteins highly related to the yeast YPT family (e.g., in maize, rice, pea, soybean, and *Arabidopsis*) suggests that the mechanisms of vesicular transport in higher eukaryotes are conserved (reviewed in Reference 417).[440–446] In maize and *Arabidopsis*, the proteins predicted from these cDNAs show high similarity to other members of the Ras family, particularly in the regions involved in GTP/GDP binding, GTPase activity, and membrane binding.[443] Further experiments using reverse-genetic analysis with antisense constructs or dominant-interfering mutations, and cytological analyses using specific antibodies, may elucidate the precise roles of YPT proteins in vesicle trafficking and plant growth.[443]

Homologs of the ARF/Sar family of GTP-binding proteins have been identified recently in *Arabidopsis* and tomato.[447–450] A clone (*A.t. Rab6*) encoding a small GTP-binding protein homologous to Rab6 of mammals has been isolated from a cDNA library of *Arabidopsis* leaf tissue.[446] The mammalian Rab6 protein (homologous to the proteins Ryh1 in *Schizosaccharomyces pombe* and YPT6 in *S. cerevisiae*) is associated with the *medial*- and *trans*-Golgi cisternae as well as with the TGN.[451,452] Disruption of the *S. cerevisiae* homolog (YPT6) results in partial missorting of vacuolar proteins,[453] indicating its participation in late events of the secretory pathway related to vacuolar targeting. Functionally, the plant gene is able to complement the temperature sensitive phenotype of the *ypt6* null mutant in yeast.[446] Characterization of this gene and its product will be awaited with interest and will allow a more complete dissection of the machinery involved in soluble protein sorting at the TGN.[446]

Secretory mutants in *A. thaliana* are presently being sought.[330] Although specific defects in transport to the plant cell vacuole are the primary focus of these researchers, a more complete set of secretory mutants may help to identify specific proteins important in mediating the various transport steps of the biosynthetic/secretory pathway. It is also noteworthy that cells of the giant alga Chara have been permealized,[454,455] and it may be possible to use this type of system to study protein secretion.[2] Compounds that stimulate or inhibit secretory events (e.g., Ca^{2+} and GTPγS, respectively) can also be microinjected into actively growing plant cells,[456] and isolation of protoplasts derived from cells that are active in protein secretion (e.g., cereal aleurone layer cells) allows analyses at the single-cell level.[457] Use of these techniques in conjunction with a molecular genetics approach should help to clarify the role of GTPases in plants.[2,458]

As noted above, GTPases of the Rab/YPT1/SEC4 family go through a characteristic cycle of reactions that drive the transition between at least two distinct conformational states (Figure 23).[459] Release of GDP from the 'inactive' (GDP-bound) state allows binding of GTP.[429,460] It then returns to the inactive state after GTP hydrolysis, an irreversible reaction that renders the cycle unidirectional. The function of GTPases as molecular switches depends on the abilities of these distinct conformational states to interact with specific macromolecules. Superimposed upon this are various regulatory or accessory proteins that control the GTPase cycle, such as guanine nucleotide dissociation inhibitors (GDI) that inhibit GDP dissociation, guanine nucleotide exchange proteins (GEP) that stimulate GDP dissociation, and the GAPs that promote GTP hydrolysis (reviewed in References 461 and 462). Recent progress has been made on the identification of these various types of accessory proteins that are specific for members of the SEC4/YPT/Rab family. A GAP that acts on YPT6 has been cloned recently from yeast by screening colonies containing high copy number plasmids with genomic inserts for increased GTPase activation.[463] Also in yeast, *Dss4* (encoding a 17-kDa protein) facilitates SEC4 protein action *in vivo* by functioning as a GDP dissociative stimulator (i.e., a GEP).[464] Likewise, studies on a *rab1* mutant suggest a cycle in which the function of a Rab1-specific GEP, which mediates guanine nucleotide exchange, is critical for recruitment of Rab1 during vesicle budding and the formation of ER and Golgi carrier vesicles competent for fusion with downstream compartments.[462] GTP hydrolysis is likely to be critical also for a late Ca^{2+}-dependent vesicle targeting fusion step controlling the delivery of vesicles to Golgi compartments.[465] Finally, a protein that acts to inhibit the dissociation of GDP from a broad range of Rab proteins has been purified from bovine brain[461,466] and yeast.[467] These proteins (termed Rab-GDI) remove Rab proteins from membranes leading to the formation of a cytosolic complex of Rab with the inhibitor protein (reviewed in Reference 391). A multistep mechanism is involved in the membrane attachment of Rab into the donor membrane (following dissociation of the Rab-GDI complex), which is mediated by a guanine-nucleotide exchange factor.[468] Thus, these various accessory proteins may function together to control each step of a functional cycle that couples GTP binding and hydrolysis to membrane attachment and recycling (Figure 21).[391,417]

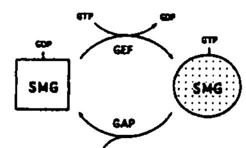

FIGURE 23. Small GTP-binding proteins as molecular switches. The switch is turned on when a small GTP-binding protein (SMG) binds to GTP with the help of GEF. GAP promotes GTP hydrolysis, which turns the switch off. (From Verma, D. P. S., Cheon, C.-I., and Hong, Z., *Plant Physiol.*, 106, 1, 1994. With permission from the American Society of Plant Physiologists.)

The current view also incorporates an interaction between Rab proteins with vesicle receptor proteins (Figure 21).[391] More specifically, receptors incorporated in the vesicle surface (v-SNAREs) may only be active for docking in the presence of the appropriate Rab protein in its GTP-bound form. Following vesicle fusion, hydrolysis of the GTP bound on the Rab protein could inactivate the v-SNARE on the target membrane. Regulation of SNAREs by Rabs could be mediated by a direct interaction, or there could be intermediates to the regulatory pathway.

F. Hormonal and Environmental Controls over Protein Secretion in Plants

The study of the effects of hormones and environmental (stress) conditions on protein transport along the endomembrane system has been hindered in large part because other "upstream" regulatory controls are often affected simultaneously (e.g., gene transcription, mRNA stability, protein synthesis, and protein folding).[4] One must also distinguish between direct and indirect effects of the altered physiological conditions on ER-mediated functions. In some cases, changes in ER function brought on by stress or hormonal changes affect the synthesis and/or transport of only a specific subset of proteins. An example is the effect of heat shock on the synthesis of seed storage proteins and their transport out of the ER.[469,470] In bean (*Phaseolus vulgaris*) cotyledons subjected to heat stress, the synthesis of phaseolin storage protein is reduced; conversely, synthesis of PHA, another major storage protein in the bean seed, is increased.[469] There is likewise an enhanced synthesis of storage proteins within developing soybean (*Glycine max*) seeds in response to heat shock.[470] In heat-shocked bean cotyledons, a large proportion of PHA accumulates in a microsomal fraction and is not transported to the Golgi complex, nor is it found in the vacuoles, the normal site of deposition of PHA. Electron-dense material accumulates within the ER cisternae in the heat-shocked cells, perhaps indicating the presence of protein aggregates. The elevated temperature may promote misfolding and aggregation of

PHA within the ER lumen, impairing its transport out of that compartment (i.e., to the Golgi complex, *en route* to the vacuole).[469] Interestingly, the heat shock is not accompanied by an increased synthesis of BiP — a protein expected to play a major role in retention of misfolded/misassembled proteins within the ER; however, other molecular chaperones playing a similar role may be induced (e.g., the low-molecular-weight Hsps).[4]

Studies on hormonal controls over protein synthesis and secretion have been most extensive on the aleurone layer of cereals (reviewed in Reference 49). The aleurone layer is comprised of small thick-walled cells that surround the starchy endosperm of the cereal grain (Figure 24). Following germination of the mature grain, these living cells secrete a large number of hydrolytic enzymes into the starchy endosperm.[49] Here, they hydrolyze and degrade the stored reserves, including polymers of the starch grains, protein bodies, and cell walls, thus providing nutrition for the enlarging and differentiating embryo. The products of this degradative process are thought to enter the embryo through uptake by the epithelial cells of the scutellum. These scutellar cells also secrete hydrolytic enzymes into the starchy endosperm following germination. The control of reserve mobilization in the cereal grain was established around 1960: the embryo produces gibberellin (GA), which induces the living cells on the periphery of the endosperm, the aleurone layer, to produce a number of enzymes. For some of these enzymes, the promotive effect of GA is on their synthesis only; for others, GA also stimulates their secretion (e.g., α-amylase, carboxypeptidase, ribonuclease, acid phosphatases).

The most well-studied enzyme, synthesized and secreted by the aleurone layer in response to GA and largely responsible for starch hydrolysis, is α-amylase, an enzyme that represents as much as 70% of the newly synthesized protein in GA_3-treated barley aleurone cells. A multitude of complex and interrelated events constitute, coordinate, and control the secretory response of the barley aleurone layer; superimposed upon the hormonal controls is a central role played by calcium, which is just beginning to be elucidated. α-Amylase is secreted from the aleurone cell along the constitutive pathway via the Golgi apparatus.[29] Following entry of the nascent protein into the lumen of the ER, the enzyme is posttranslationally modified in a number of ways. Two of these modifications (that may be related) are the folding of the protein into a specific and functional three-dimensional conformation and the addition of Ca^{2+}.[471] Barley α-amylase is a Ca^{2+}-containing metalloprotein whose activity and stability are dependent on the binding of at least one atom of Ca^{2+} per mole of α-amylase. Both the folding of α-amylase into a functional three-dimensional conformation and the addition of Ca^{2+} may be regulated by the ER-resident, BiP (see below). Ca^{2+} binding also leads to a marked change in the tertiary structure of the α-amylase molecule, as shown by changes in tryptophan fluorescence following the removal of bound Ca^{2+} from the protein.[34]

The dependence on Ca^{2+} for activity/stability of α-amylase has impeded elucidation of the precise role of Ca^{2+} on synthesis/secretion of the enzyme;[472] nonetheless, considerable progress has been made in the last 5 years. Less than 1% of the Ca^{2+} needed for the synthesis of active α-amylase is available within the aleurone cell.[473] Ca^{2+} binding to α-amylase is estimated to require a Ca^{2+} concentration of at least 10 μM within the ER lumen; thus, the synthesis and secretion of α-amylase by isolated aleurone layers is highly dependent upon the supply of external Ca^{2+} required at millimolar concentrations (e.g., 10 mM). Although synthesis and secretion of α-amylase is promoted by GA_3 in the presence of Ca^{2+}, this process is prevented by abscisic acid (ABA). Controls by GA and ABA with respect to induction or suppression of α-amylase synthesis and secretion by isolated aleurone layers appear to be exerted in part at the level of transcription. The 5′ upstream *cis*-acting sequences responsive to ABA and GA have been identified in α-amylase genes, and the *trans*-acting factors (DNA-binding proteins) potentially involved in regulating gene expression are being characterized.[474–478] However, hormonal controls over α-amylase synthesis and secretion exist at additional (posttranscriptional) levels; these controls in turn appear to be intimately related to the requirement for Ca^{2+}. These various controls (Figure 25) (reviewed in Reference 34) include the following:

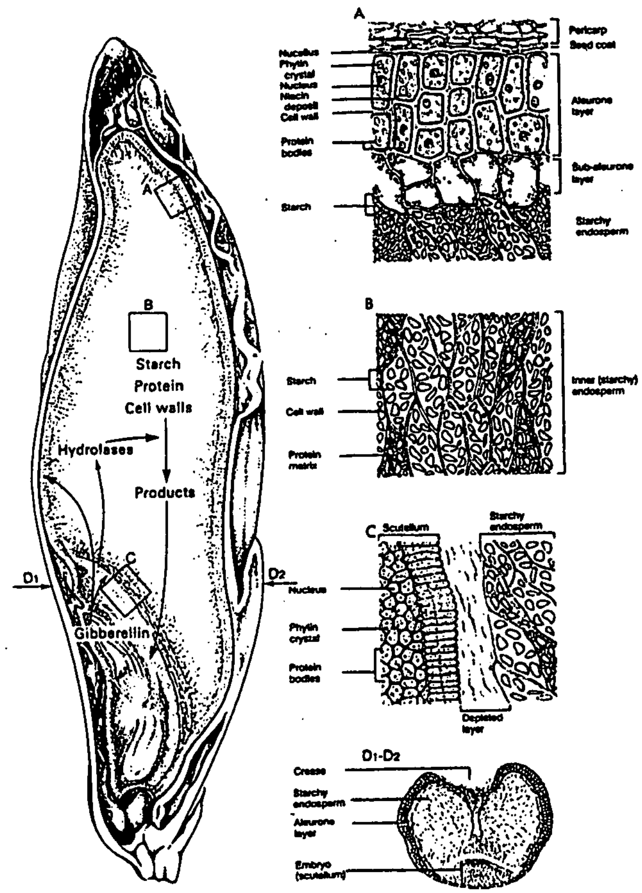

FIGURE 24. The structure of the barley grain. On the left is a longitudinal section of the whole grain. (A) The aleurone and sub-aleurone layers. (B) Endosperm cells. (C) The interface between the scutellum and the endosperm. (D 1–2) Transverse section through the grain where the embryo and endosperm overlap. (From Jones, R. L. and Jacobsen, J. V., *Intl. Rev. Cytol.*, 126, 49, 1991. With permission from Academic Press.)

1. GA and ABA control calcium homeostasis in aleurone cells. GA has a profound effect on the flux of Ca^{2+} into the aleurone cell, which is increased by approximately tenfold, possibly as a consequence of the hormone stimulating the opening of channels in the plasma membrane and/or preventing efflux of Ca^{2+} from the cytosol. The GA-

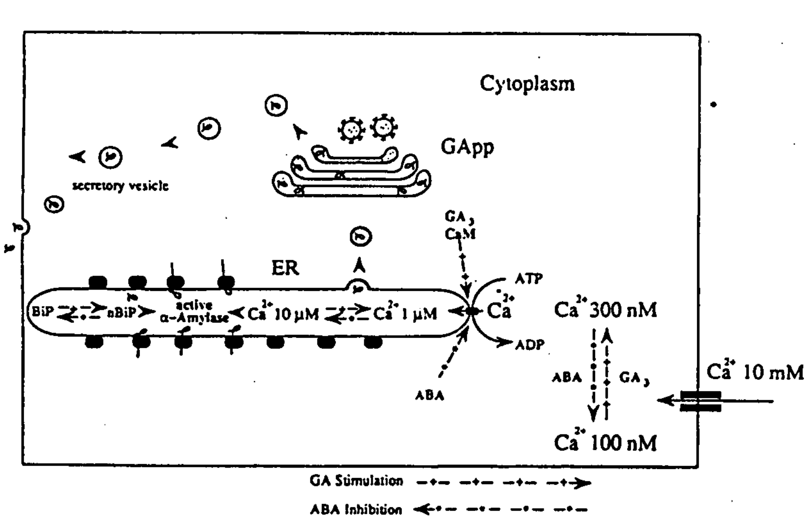

FIGURE 25. Model of the calcium-dependent events occurring during hormonal regulation of secretory activity in the barley aleurone cell. (From Jones, R. L., Gilroy, S., and Hillmer, S., *J. Exp. Bot.*, 44 (Suppl.), 207, 1993. With permission from Oxford University Press.)

induced change in cytosolic Ca^{2+} is most pronounced within the periphery of the cytosol and precedes the onset of α-amylase synthesis and secretion. ABA reversal of GA-induced α-amylase synthesis is preceded by a lowering of cytosolic Ca^{2+} levels.[479]

2. GA and ABA regulate calcium uptake into the ER. The two hormones appear to regulate Ca^{2+} uptake by the ER at several levels. First of all, the activity of an ATP-dependent Ca^{2+} transporter located on the ER membrane of barley aleurone cells is stimulated by GA and inhibited by ABA.[480] Increased cytosolic Ca^{2+} may play an important role in regulating the transport of Ca^{2+} into the lumen of the ER *in vivo*; the increase as a consequence of GA_3 treatment likely stimulates the activity of the Ca^{2+} pump. As a consequence, the ER can accumulate millimolar levels of calcium.[479,481] GA also increases calmodulin (CaM) levels in the aleurone cell, which presumably further activates the ER Ca^{2+} transporter.[482] The increased Ca^{2+} flux into the ER supports the synthesis of α-amylase (a calcium metalloprotein), and also activates and stabilizes the molecule.[34] The accumulation of Ca^{2+} in the ER may be facilitated further by the presence of Ca^{2+}-binding proteins within the ER lumen that also play roles as molecular chaperones. The amount of a BiP cognate within the ER lumen of barley aleurone cells is elevated by GA and reduced by ABA.[273] Thus, BiP may play an important role in allowing the ER to accumulate Ca^{2+}, in addition to aiding in the folding of the α-amylase molecule. These various controls would be expected to affect α-amylase transport and secretion because secretory proteins are generally not competent for transport out of the lumen of the ER until they have assumed the correct three-dimensional conformation.

3. Calcium and CaM may act as secondary messenger molecules mediating hormone-induced changes in ion channel activity. The activity of a slow vacuolar (SV) ion channel in the tonoplast of barley aleurone storage protein vacuoles is increased in protoplasts treated with GA_3, and decreased in the presence of ABA.[41] The opening of the channel is sensitive to cytosolic-free Ca^{2+} concentrations $[Ca^{2+}]_i$ between 600 n*M* and 100 μ*M*. Ca^{2+} may activate endogenous CaM that is tightly associated with the membrane; CaM also sensitizes the SV channel to $[Ca^{2+}]_i$. The function of this particular SV channel in barley aleurone cells is unknown; it may be involved in mobilization of stored K^+ from the aleurone cells to the embryo following germination. Nonetheless, these results indicate that the SV channel, like the plasma membrane and ER Ca^{2+}-ATPases, is a plant ion transporter regulated by Ca^{2+}-CaM. Because GA regulates both $[Ca^{2+}]_i$ and CaM levels in barley aleurone cells, Ca^{2+} and CaM are proposed to act as signal transduction elements mediating hormone-induced changes in ion channel activity.[41] The mechanism of the CaM effect on channel gating (e.g., via a kinase or phosphatase) is being investigated presently.[41]

In summary, by regulating the elements involved in the signal transduction pathway, phytohormones can regulate the synthesis and secretion of the α-amylase molecule.[34] Identification of GA and ABA receptors has not been achieved yet. However, recent studies have yielded convincing evidence that GA and ABA are perceived initially on the external face of the plasma membrane (see review by Allan and Trewavas[483]). For example, barley aleurone protoplasts respond to GA_3 and ABA applied extracellularly, but not to hormone microinjected into the cytosol of the cell;[484] membrane impermanent GAs have biological activity (i.e., are capable of eliciting α-amylase synthesis) in oat protoplasts, also indicative of a surface receptor for GA action.[485] Elucidation of the entire signal transduction pathway (e.g., possible regulation of G protein activity following hormonal perception) will be awaited with interest. Some of the events that GA triggers may be specific to α-amylase production and secretion. For example, in contrast to α-amylase, a fusion protein consisting of the inert marker molecule PAT linked to a signal peptide, is secreted efficiently when synthesized transiently in barley aleurone protoplasts treated with ABA.[486] Because secretion was equally efficient in ABA-treated vs. GA-treated protoplasts, ABA does not have an adverse effect on the general capacity of aleurone cells for secretion.

G. Signal-Mediated Sorting of Proteins to the Plant Cell Vacuole and Retention in ER-Derived Protein Bodies

As mentioned previously, the plant cell vacuole is a multifunctional compartment; its functional diversity arises in part from the strict spatial and temporal regulation of the genes encoding soluble and membrane proteins destined to reside there (reviewed in Reference 18). The central vacuole of mature plant cells occupies more than 80 to 90% of its total volume; one of its major roles is to regulate turgor, important for the mechanical stability of plants. Vacuoles of many cells are used as an intermediate storage compartment for ions, sugars, and amino acids; in these cell types there is a regular exchange of these compounds between the cytosol and vacuole. Carrier or channel proteins located within the vacuolar membrane (tonoplast) often mediate this exchange, in which the driving force for uphill transport can be a proton gradient generated by tonoplast-associated H^+-ATPases and H^+-pyrophosphatases.[18] Vacuoles of other plant cell types serve as storage depots, such as those for storage of defense proteins and allelochemicals, or for storage proteins.

1. *Mechanisms of Storage Protein Deposition in Seeds*

Transport and targeting of proteins to the plant cell vacuole have been investigated most extensively in seeds, particularly in relation to the synthesis and deposition of storage proteins (reviewed in References 12, 17, 83, and 487 through 492). As mentioned previously, within many seeds,

vacuoles perform a dual function — as temporary storage depots (during seed development) and as sites of macromolecular hydrolysis (during postgerminative seedling growth). The synthesis and deposition of seed storage proteins are subject to strict temporal and spatial regulation; they only occur in specific tissues/organs and only at specific times during seed development. Cell expansion and deposition of reserves (including storage proteins), follow the histodifferentiation stage of seed development, and occur largely in the absence of further cell divisions (reviewed in References 35 and 36). It is during this time that young storage parenchyma cells (particularly within the major reserve organs of seeds — the endosperm, cotyledons, or megagametophyte) accumulate a variety of proteins, including storage proteins, acid hydrolases, plant defense proteins, and other reserve materials or metabolites in storage compartments (organelles) called protein bodies.[330] In vegetative tissues, leaf and bark storage proteins accumulate in vacuoles that resemble the protein bodies of seeds (Figure 26).[23,493]

It is noteworthy to mention here that there are distinct pathways of protein body formation in seeds (Figure 26). One pathway that is characteristic of most dicotyledonous seeds involves the subdivision or fragmentation of a large central vacuole. In this mechanism of protein body formation, which also appears characteristic of the gymnosperm seeds studied so far,[494,495] storage proteins are deposited into subdividing vacuoles (protein bodies) via transport through the Golgi complex (e.g., rice globulins [glutelins], wheat prolamins, and legume globulins). The globulins of leguminous seeds are likely soluble in the ER and undergo subsequent transport to the vacuole (via the Golgi complex) as soluble components. However, after arrival at the vacuole, they likely precipitate due to the low pH of the vacuole (and possibly also as a result of proteolytic processing) (reviewed in Reference 489; see references therein). A second mechanism occurs in some cereals and involves direct formation of protein bodies from the rough ER (reviewed in References 488, 489, and 496 through 500). Here, storage proteins are synthesized on the rough ER and are deposited directly within the lumen of this organelle, where they remain and accumulate (e.g., prolamins of maize, rice, and sorghum). There is now evidence for yet another route (e.g., for some of the wheat prolamins), which begins by assembly of the proteins into protein bodies within the ER. However, these ER-derived protein bodies undergo subsequent internalization within vacuoles by a specific process analogous to autophagy.[4,488,489] Thus, the wheat prolamin storage proteins exhibit two pathways or routes of transport to protein bodies.

2. Biogenesis of ER-Derived Protein Bodies and Mechanisms of Protein Retention

In many cereals (e.g., maize, rice, and sorghum), the prolamins are retained within the lumen of the rough ER to form protein deposits that remain surrounded by the ER membrane (Figure 26C).[501–503] In contrast, the prolamins of other cereals, such as wheat, barley, and oats accumulate (along with globulins) in vacuole-derived protein bodies, and in most cases transit through the Golgi complex to arrive there. Rice seeds accumulate two types of storage proteins — the globulin-like glutelins and the prolamins; the former are transported to vacuoles via the Golgi complex, whereas the latter aggregate within the ER lumen.[502,504] These different pathways exhibited by the two storage protein types appear to be facilitated by a differential targeting of their respective mRNAs onto distinct rough ER membranes.[505] During the period of storage protein deposition and protein body biogenesis, the endosperm cells exhibit two morphologically distinct populations of ER membranes: the cisternal ER and the ER that delimits protein bodies (protein body ER). Analyses of the spatial distribution and densities of the specific mRNAs in subcellular fractions enriched in these two ER types reveal a nonrandom distribution. Notably, prolamin transcripts are enriched on the rough ER that delimits the prolamin protein bodies, whereas glutelin mRNAs predominate on the cisternal ER.[505] The molecular basis for segregation of prolamin transcripts to the surface of the protein body ER is presently unknown, although specialized signal peptides and/or components involved in their recognition (i.e., SRPs or ER membrane proteins) have been suggested to play a role.[489,505]

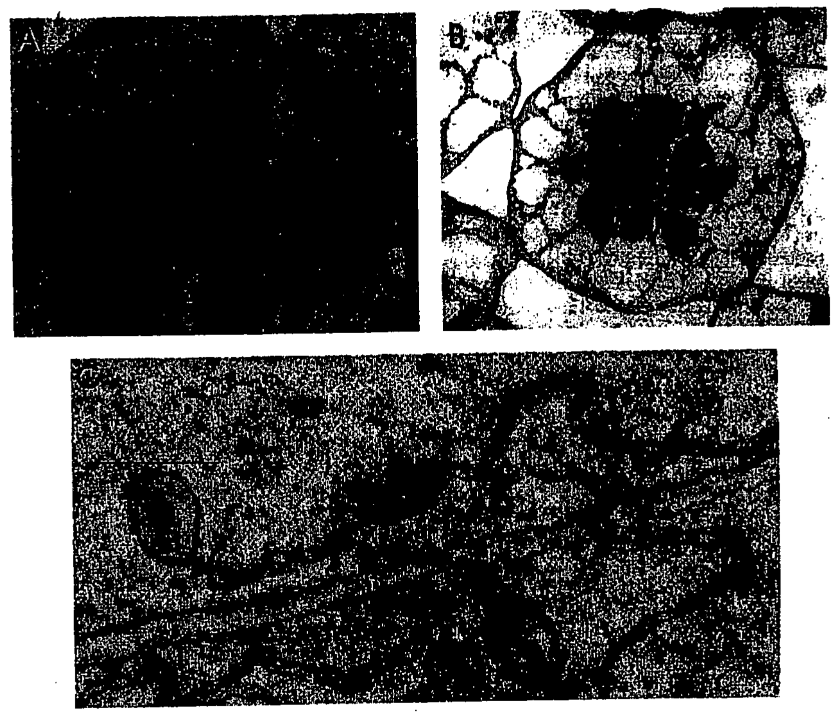

FIGURE 26. Vacuoles and protein bodies in vegetative and seed tissues. (A) Vacuoles within the leaves of *Sophora japonica* trees. The vacuoles are partially or completely filled with protein, including the well-characterized leaf lectins. N, nucleus; C, chloroplast; V, vacuole. For details, see Herman et al.[493] (From Herman, E. M., Hankins, C. N., and Shannon, L. M., *Plant Physiol.*, 86, 1027, 1988. With permission of the American Society of Plant Physiologists. Courtesy of E. M. Herman.) (B) Electron micrograph of a cell from a developing pea cotyledon. Numerous protein storage vacuoles are visible. Storage protein is being accumulated as electron-dense deposits at the periphery of the PSVs. At the end of seed development, PSVs will be completely filled with protein. The nucleus is at the center, surrounded by large, electron-dense, starch grains. (From Vitale, C. and Chrispeels, M. J., *Bioessays*, 14, 151, 1992. With permission from ICSU. Courtesy of S. Craig, CSIRO Plant Industry Division.) (C) Protein bodies originating from the rough ER. Electron micrograph of a developing cell of the starchy endosperm of maize to illustrate the formation of protein bodies (PB) forming from rough endoplasmic reticulum (RER) and the proximity of membrane-bound polyribosomes (MBP). Note the continuity between the protein body membranes and extended RER cisternae (arrow). CW, cell wall. See Larkins and Hurkman.[501] (From Larkins, B. A. and Hurkman, W. J., *Plant Physiol.*, 62, 256, 1978. With permission from the American Society of Plant Physiologists. Courtesy of B. Larkins.)

Another intriguing possibility is that elements of the cytoskeleton are involved. There is a close association of actin filaments with the prolamin-type protein bodies of maize,[506] and a role for the cytoskeletal framework in protein synthesis is firmly established.[507] F-actin may facilitate prolamin-protein body biogenesis by facilitating interaction of prolamin mRNAs with the protein body-

ER. Nonrandom deposition of prolamins may also occur within the endosperm of developing maize, where specific prolamin types are inserted sequentially into protein bodies; correct assembly of different types of prolamins may be required for the formation of normal protein bodies (see Reference 489 and references therein). For example, when individual maize prolamins are expressed in *Xenopus* oocytes, the protein bodies that form have a lower density than that of protein bodies containing all prolamin types (see subsequent discussion, Section VIA, and Reference 602). Although maize prolamin is normally accumulated in ER-derived protein bodies, when expressed in seeds of a heterologous plant host (tobacco) that exhibit protein body biogenesis from subdividing vacuoles, the protein is transported successfully to the vacuole.[507a] Thus, in some cases, maize prolamin is able to escape the normal retention process (but see also Reference 507b).

What, then, is the mechanism of retention of storage proteins within the ER? Is it due to their intrinsic structure or physical properties, or do specific ER-factors also play a role? The conventional mechanism for retention of soluble proteins within the ER is the carboxy-terminal tetrapeptide sequence KDEL or HDEL. Yet, it is unlikely that the mechanism involves this specific retention signal because it is not present on any of the storage proteins that are retained in the ER. Evidence suggesting that the retention mechanism is partly a function of the mature protein comes from expression studies utilizing heterologous hosts (e.g., yeast or *Xenopus* oocytes), in which cereal prolamins are efficiently retained. For example, injection of zein mRNAs into *Xenopus* oocytes results in the synthesis, processing and accumulation of the storage proteins within the ER and assembly into membrane-enclosed structures with the physical characteristics of protein bodies from cereals.[508,509] Failure of prolamins to be secreted from animal cells is not due to improper recognition/processing of the signal peptide or inefficient sequestration into the membrane of the rough ER.[510]

In rice seeds, specific factors in the ER appear to play a pivotal role in protein retention. Here, the ER molecular chaperone BiP retains prolamins within the ER lumen by promoting the folding and assembly of prolamins into protein bodies.[504] Within developing endosperm cells, BiP is localized on the surface of aggregated prolamin protein bodies; dissociation of BiP from these bodies is an ATP-dependent process. It is proposed that biogenesis of protein bodies is a sequential process mediated by BiP. According to this model, BiP binds to the nascent prolamin as it emerges through the ER membrane, an interaction that serves to maintain the polypeptide in a competent state for subsequent assembly into protein bodies. Following the completion of protein synthesis, the prolamin-BiP complexes are released into the ER lumen, and BiP utilizes ATP to assemble the prolamins onto the protein body surface; dissociated BiP is then recycled. A critical concentration of BiP-prolamin complexes within the ER lumen may trigger the initiation of the BiP-mediated aggregation process. Interestingly, BiP has a higher affinity for rice prolamins than it does for rice glutelins, possibly due to the greater proportion of aliphatic amino acids in the former.[511] Although BiP likely associates transiently with glutelins within the ER lumen, it is not localized to the surface of the cisternal ER where glutelins are synthesized.[504,505] The involvement of BiP in prolamin protein body formation is also supported by its elevated concentration in the protein bodies of maize mutants defective in zein accumulation.[137] It is not yet clear whether this mechanism involving a specific ER-associated component (BiP) operates for the retention of other cereal storage proteins that accumulate in ER-derived protein bodies. Retention mechanisms may also involve the physical characteristics of the protein, preventing subsequent transport following translocation into the ER.

The structures of cereal prolamins have been characterized in detail (reviewed in Reference 489; see references therein).[512,513] Most of the prolamins contain several small amino acid repeats that are rich in glutamine and proline. In the sulfur-poor prolamins of wheat, barley and rye, and the α-zeins of maize, these repeats comprise almost the entire length of the polypeptide. In contrast, the sulfur-rich (S-rich) prolamins and the high-molecular-weight prolamins of wheat, barley, and rye contain the repetitive region, but, in addition, contain a 'unique-sequence' globular

region at their C-terminus, which is enriched in α-helices and contains several intramolecular disulfide bonds. Expression of the wild-type S-rich γ-gliadin from wheat and two deletion mutant forms of the protein (missing either the N-terminal or C-terminal regions) in *Xenopus* oocytes has provided some information regarding the possible role of the different regions in protein sorting.[514] When intact γ-gliadin protein is synthesized in *Xenopus* oocytes, a certain proportion of the protein is retained within the ER, while some of the protein is secreted. A deletion mutant composed of only the N-terminal repetitive region of γ-gliadin is retained and packaged into ER-derived protein bodies. Conversely, presence of the C-terminal region leads to efficient secretion from *Xenopus* cells. Thus, sorting of wheat γ-gliadin is proposed to be determined by a balance between two opposing signals: (1) the effectiveness of the N-terminal repetitive region that is responsible for ER retention and assembly into protein bodies within the ER, and (2) the counteracting effect of the C-terminal 'unique-sequence' region that averts packaging within the ER and renders the polypeptide competent for export to the Golgi complex.[514] Moreover, these studies suggested that the retention signal is probably related to the secondary structure of the repetitive region, rather than to its primary structure,[489] although exposed glutamine residues as well as other amino acids present on S-rich prolamins may contribute to the retention process through hydrophobic and hydrogen-bond interactions.

Different retention mechanisms may operate for the maize prolamins, specifically β-, γ-, and δ-zeins, that lack the N-terminal repetitive domain characteristic of maize α-zeins. Localization of γ-zein and truncated forms of γ-zein in *Xenopus* oocytes was determined to examine the role of cysteine-rich domains in ER retention.[515] One truncated zein was deleted in a 94-amino acid C-terminal Cys-rich domain, and the other lacked a 21 amino acid Pro-X linker region that links the Cys-rich domain to a Pro-rich domain. Both truncated forms (as well as intact γ-zein) were efficiently accumulated in *Xenopus* oocytes, indicating that structural features derived from disulfide bonds are not necessary for the retention mechanism of these proteins.[515]

Thus, retention in ER-derived protein bodies in cereals may involve multiple mechanisms, and these mechanisms may interact (e.g., BiP-mediated assembly/aggregation and physical characteristics of the protein, preventing transport out of the ER).

3. Evidence for an Alternative Routing Mechanism to Vacuole-Derived Protein Bodies in Cereal Seeds that Bypasses the Golgi Complex

The transport of prolamins to vacuoles has been studied most extensively in the endosperm of developing wheat grain. In this system, Golgi-derived vesicles contain prolamins, indicative of a route to the vacuole that involves transport through the Golgi complex. However, there is now evidence for an alternative route of prolamin transport to the vacuole that bypasses the Golgi complex. Thus, a considerable proportion of the wheat prolamins assemble into protein bodies within the rough ER. However, there is a subsequent transport of these intact protein bodies to the vacuole where they become internalized by a process analogous to autophagy (Figure 27) (reviewed in References 489, 516, and 517). This process appears to be initiated as protein bodies disconnect from the cisternal ER, an event sometimes accompanied by rupture of the ER membrane. Small electron-lucent vesicles (of unknown origin) then attach and encircle the surface of the protein body, and fuse forming a vacuole containing a protein-body inclusion. In many cases protein bodies inside vacuoles are surrounded by one or two membranes in addition to the vacuolar membranes, suggesting that internalization may occur by an autophagy-like process.[517] Interestingly, a wheat BiP homolog is present within the protein bodies in the cytoplasm as well as inside vacuoles, indicating a Golgi-independent route. It has yet to be determined whether the two routes of transfer of prolamins also operate in other cereals, such as barley and oats. Prolamins of barley may exhibit similar pathways; in the developing endosperm, the constituent protein bodies are surrounded by membranes inside vacuoles (see Reference 489 and references therein). Likewise,

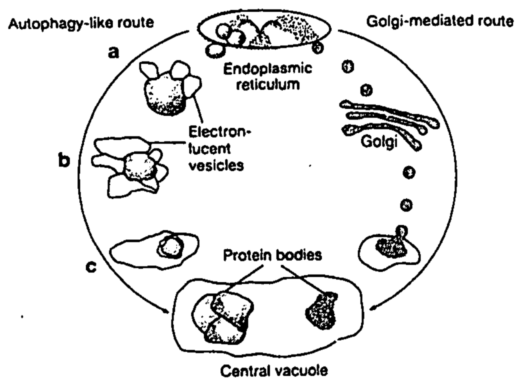

FIGURE 27. Schematic representation of the two different routes by which wheat prolamins transit to vacuoles. Right: The paradigm route, including vesicular transport from the ER via the Golgi complex to vacuoles. Left: Protein bodies formed within the ER become surrounded by electron-lucent vesicles and are internalized into vacuoles by a process analogous to autophagy. (From Galili, G., Altschuler, Y., and Levanony, A., *Trends Cell Biol.*, 3, 437, 1993. With permission from Elsevier Publishing, Cambridge.)

despite the general accumulation of oat prolamins in conventional vacuole-derived protein bodies, some oat prolamins are also detected in protein bodies surrounded by rough ER.

4. Expression of Storage Proteins in Heterologous Hosts: Universality of Targeting Machinery

Because there is such a striking conservation of both general and specific features of the secretory pathway in eukaryotic cells, a pertinent question that has been addressed is whether plant vacuolar targeting signals are correctly processed in other eukaryotes. Plant vacuolar proteins expressed in animal cells (e.g., monkey COS cells, *Xenopus* oocytes) and insect cells, generally undergo normal cotranslational and posttranslational processing that includes signal peptide cleavage and glycosylation; however, they are not retained in any subcellular compartment, but rather are secreted by the bulk-flow pathway.[510,518–520] This further indicates that signals for targeting proteins beyond the Golgi apparatus in plant cells are different from those in animal cells. Not surprisingly, secretion is the outcome only for plant storage proteins that normally transit to their target organelles (vacuoles) via the Golgi complex; as mentioned previously, proteins exhibiting the other major mechanism of transport (i.e., involving deposition into the ER, and subsequently aggregation and formation of the protein body) are retained when expressed in animal cells. Expression of the wheat storage proteins, α-gliadin and γ-gliadin in *Xenopus* oocytes leads to their partial secretion via the Golgi complex; however, secretion occurs at considerably different rates (i.e., at a much faster rate for γ-gliadin), indicative of the different pathways transited by these related wheat storage proteins.[510,514] Some of the features of the plant vacuolar transport and targeting machinery are similar to those of yeast. In those cases studied, when storage protein genes (e.g., PHA) are expressed in yeast cells, the majority of the protein is transported to the vacuole.[521] Some features of vacuolar targeting, then, are conserved in these two highly divergent species. However, although yeast has been used as a model system to attempt to identify plant vacuolar targeting signals, these attempts have largely met with failure. Furthermore, protein sequences or domains on plant proteins that lead to vacuolar targeting in yeast do not function in the same manner in plants and vice versa. Thus, although some components of the targeting pathway are conserved between animals, plants, and yeast (e.g., GTP-binding proteins), other components (e.g., targeting receptors) may be unique.[488]

5. Vacuolar Targeting in Yeast: Genetic and Biochemical Studies

The yeast vacuole, like the plant cell vacuole, is an acidic compartment that functions as a lytic site; it also serves as a storage depot for amino acids, phosphate, and inorganic ions. Numerous soluble hydrolytic enzymes reside in this organelle, including carboxypeptidase Y (CPY), proteinase A (PrA) and proteinase B (PrB). Its limiting membrane also contains a number of proteins and protein complexes, including α-mannosidase, alkaline phosphatase (AlP), dipeptidyl amino-peptidase B (DPAP B), a proton-translocating ATPase, and several permeases.

The soluble vacuolar hydrolases of yeast have been well characterized in terms of their biosynthesis. These proteins are synthesized as inactive precursors (preproproteins) with N-terminal signal peptides that are proteolytically removed during translocation into the ER. Core glycosylation occurs in the ER; additional carbohydrate modifications take place during their transit through the Golgi complex. Sorting of vacuolar enzymes occurs in a late Golgi compartment. Coincident with or just prior to their arrival in the vacuole, the modified precursor proteins (e.g., proCPY, proPrA, and proPrB) are activated by the proteolytic removal of a propeptide segment, a maturation process dependent upon the hydrolase PrA.[522] Considerable progress has been made in characterizing the vacuolar sorting signals of these soluble hydrolases (reviewed in References 364, 523, and 524). In the absence of positive sorting signals for directed targeting away from bulk flow, proteins traversing the yeast secretory pathway are delivered to the cell surface. This fact was exploited to design a screen for mutations in the CPY structural gene (*pcr1*) that result in secretion of CPY.[525,526] Another approach was to construct a nested set of carboxy-terminal deletions in CPY fused to invertase and to follow the fate of the chimeric proteins.[527] This approach demonstrated that the amino-terminal 50 amino acids of the CPY preprodomain, which includes a 20-residue signal peptide, are sufficient to sort invertase protein to the vacuole, while the first 30 amino acids direct high levels of secretion. Deletion analysis of the CPY gene (*pcr1*) in the propeptide-encoding region implicated a domain in the vicinity of amino acid 28 that is essential for efficient sorting of pro-CPY to the vacuole.[526] Deletions in this domain cause the mutant protein to bypass the Golgi sorting reaction and result in mislocalization of most of the proCPY to the cell surface. The analysis of point mutations in the *pcr1* gene, encoding amino acid residues Lys 18 (in the signal sequence) to Leu 34, identified only four contiguous residues important for vacuolar sorting, $LQRP_{26}$ (Leu-Gln-Arg-Pro).[526,528] Thus, this tetrapeptide sequence constitutes the core of an amino-terminal topogenic element, immediately following the signal peptide, that is necessary for targeting proCPY to the yeast vacuole.[523] Interestingly, the context in which the CPY tetrapeptide sequence is presented affects the efficiency of targeting, inferring the involvement of secondary structural elements in the sorting mechanism of this protein.[528]

Subsequent analysis of the targeting signals of other vacuolar soluble hydrolases (e.g., PrA and PrB) revealed that the sorting mechanisms in yeast are much more complex than the initial simplistic model that emerged from the CPY studies. The sorting domain of these proteins is unlikely to be a short linear amino acid sequence. For PrA it may be encoded by two signals, one in the mature protein and the other in the propeptide domain (e.g., between amino acids 61 and 76).[529] There is no sequence similarity between the propeptides of CPY and PrA. Thus, currently no consensus sequence or common structural determinant has been demonstrated for yeast vacuolar

proteins, suggesting that a diverse array of factors may be operative in the sorting process. Although not clearly defined, the sorting domain of PrB likely resides in the mature portion of the protein because the precursor undergoes an unusual early processing event in which the 280 amino acid propeptide is removed in the ER.[530]

Although some commonalities exist, there are independent mechanisms for the delivery of soluble and membrane proteins to the yeast cell vacuole. This appears to be the case for sorting of the vacuolar (type II) integral membrane protein AIP.[531] Transport of this protein is less sensitive to some of the defects of the vacuolar sorting apparatus in mutants that exhibit dramatic missorting and secretion of the soluble hydrolases (e.g., CPY and PrA; see subsequent discussion). DPAP B also resides in the yeast vacuole as a type II integral membrane protein having short (amino-terminal) cytoplasmic and transmembrane domains (of 45 amino acids in total) and a large (800 residues) luminal domain.[532] No single domain of DPAP B is required for delivery to the vacuolar membrane. Removal or replacement of either the cytoplasmic transmembrane or luminal domain does not affect the protein's transport to the vacuole.[533] DPAP A normally resides in the yeast Golgi complex; both overproduction of this protein and a mutation within its cytoplasmic domain result in mislocalization to the vacuole. These results have invoked a model in which membrane proteins are delivered to the vacuole along a default pathway.[533] Interestingly, α-mannosidase, a marker enzyme of the vacuolar membrane in yeast, is delivered to the vacuole by a novel route separate from the secretory pathway.[534]

It is likely that yeast vacuolar protein targeting signals are recognized by a sorting receptor(s), and the resultant receptor-ligand complexes are subsequently sorted into vesicles and transported to the vacuole by additional constituents of the vacuolar sorting machinery. Toward identifying the components of this sorting process, the application of several genetic selections has resulted in the isolation of a number of mutants that exhibit defects in vacuolar protein localization (primarily of the soluble hydrolases) and/or processing (reviewed in Reference 523). Instead of delivering vacuolar hydrolases to the vacuole, these *vps* (vacuolar protein sorting defective) mutants missort the enzyme precursors to the yeast cell surface.[523,535–537] Posttranslational glycosylation and secretion of proteins is normal in most mutants; thus, their defects are specific for targeting to the vacuole.[535,536] Genetic comparisons among the *vps* mutants demonstrate that they collectively define more than 50 unique complementation groups, indicating that delivery of proteins to the yeast cell vacuole represents a highly complex process requiring the coordinated participation of a relatively large number of gene products. Some of these components are likely to include sorting receptors and proteins involved in the formation, interorganelle transport, targeting, and fusion of vesicles. Biochemical characterization of the *vps* mutants should not only identify cellular components directly involved in the specific segregation, packaging, and delivery of vacuolar proteins, but also those gene products involved in the regulation or control of these processes.

Progress toward this goal has been achieved recently with the characterization of protein products of some *vps* mutants (Table 9). The VPS1 protein is homologous to a group of proteins with a GTP-binding motif, some of which also bind microtubules.[538] Another VPS protein, VPS15, is a serine/threonine kinase that is essential for the delivery of soluble hydrolases to the vacuole.[539,540] The VPS15 protein is preferentially associated with the cytoplasmic face of a late Golgi or vesicle compartment and may regulate specific protein phosphorylation reactions required for efficient delivery and sorting of proteins to the yeast cell vacuole. For example, mutational alteration of the VPS15 protein kinase domain results in the biological inactivation of this protein and the secretion of multiple vacuolar hydrolases. Protein phosphorylation has been implicated as a key regulator of protein sorting, specifically acting within pathways at branch positions, where proteins must choose between two or more different transport fates.[539,541,542] Thus, the proposed role of protein phosphorylation is as a molecular "switch" within intracellular transport pathways such that proteins are actively diverted from a default pathway (i.e., secretion) to an alternative pathway (e.g., transport to the vacuole). In carrying out its role,

TABLE 9
Genes that May Function in the Transport and Sorting of Proteins to the Yeast Vacuole[a]

Gene	Phenotype	M_r (kDa)	Sequence features	Protein features and localization[c]	Protein function *in vitro*
vps1	Golgi membrane, multivesicular bodies; secretes vacuolar proteins	80	Identity with *S.c.* SPO15, similar to *D.m.* shibire[b]	Punctate localization	GTP-binding
vps3	Secretes soluble vacuolar proteins	140	—	Partially soluble protein	—

the VPS15 protein appears to functionally interact with another protein that is encoded by the gene *vps34*.[539,543] The VPS34 protein is a phosphatidylinositol 3-kinase involved in the formation of 3-phosphorylated phosphoinositol-phosphates and known to interact with activated cell surface receptor tyrosine kinases.[544] VPS34 is thought to be present in an unknown intermediate organelle where sorting to the vacuole may occur. Point mutations altering highly conserved residues within the VPS34 kinase domain result in inactivation of VPS34p/PI3-kinase and missorting and secretion of vacuolar proteins, confirming the role of this protein in regulating intracellular protein trafficking decisions. The presence of phosphoinositides in the lipid bilayers of organelles and vesicles may allow fusion of transport vesicles with their target membranes or enable binding of cytosolic and/or cytoskeletal proteins to transport vesicles (reviewed in Reference 396). Recently, a plant homolog of the yeast *vps34* gene has been isolated.[545]

The mechanism or level of control involving phosphorylation may be superimposed upon that carried out by GTP-binding proteins (viz., mediating the unidirectionality of secretory protein traffic and designating a transport vesicle's final destination; see earlier discussion).[539] Three

genes, *ypt51*, *52*, and *53*, have been isolated from *S. cerevisiae* that encode small GTPases with extensive homology to mammalian Rab5 and the *S. pombe* YPT5 protein.[546] The defects associated with single, double, and triple null mutants of *ypt51*, *ypt52*, and *ypt53* suggest an important function of the encoded proteins in the delivery to the vacuole of two endocytic markers, α-factor and lucifer yellow CH. Moreover, a number of vacuole-related defects associated with the *ypt* mutants such as protein sorting, acidification, and morphological changes, are indicative of a key role for these YPT proteins in vacuole biogenesis.[546] In developing pumpkin cotyledons, small GTP-binding proteins are associated with dense vesicles targeted to vacuoles. Studies are underway to determine whether these proteins play a pivotal role in vesicle targeting and/or fusion to the plant vacuolar membrane.[547]

Vps16 gene function leads to severe defects in the sorting of soluble and membrane-associated vacuolar proteins and greatly perturbs vacuole morphology.[548] Fractionation studies indicate an association of the VPS protein with a large proteinaceous complex that is required for vacuole biogenesis and/or vacuole stability. It may also associate with a limited number of sites on cytoskeletal elements.

The generation and maintenance of a low luminal pH within organelles of the secretory pathway is critical for vacuolar sorting (reviewed in References 523 and 524). Specifically, acidification is presumed to play a role in promoting the dissociation of vacuolar proteins from their sorting receptors, allowing the unbound receptors to return to the Golgi complex. Agents that abolish acidification of the vacuolar lumen (e.g., ammonium chloride, a classic lysosomotropic agent, or balifinomycin A1, a specific and potent inhibitor of vacuolar H^+-ATPases) also promote mislocalization of newly synthesized vacuolar proteins to the cell surface.[549,550] Presumably, these agents result in the recycling of bound receptors, causing a depletion of the pool of receptors available for sorting; secretion of newly synthesized vacuolar proteins by bulk-flow transport is the outcome. The yeast vacuolar H^+-ATPase is a multimeric enzyme containing at least 8 subunits of 100, 69, 60, 42, 36, 32, 27, and 17 kDa (see References 551 through 554 and references therein). Most of the structural genes encoding these subunits have been cloned. The 69- and 60-kDa proteins bind ATP and are thought to form the catalytic site, whereas six copies of the 17-kDa protein are thought to form the proton channel (reviewed in Reference 555); other proteins participate in the assembly and localization of the vacuolar H^+-ATPase complex.[523,551,553,554] For example, the protein Vma21 is an ER membrane protein required for assembly of the vacuolar H^+-ATPase complex.[551] The 42- and 27-kDa subunits are essential for assembly of the peripheral membrane portion of the H^+-ATPase onto the vacuolar membrane.

The analyses of plant cells defective in H^+-ATPase activity (pH mutants) will allow a direct test of the role of acidification in the sorting of plant vacuolar proteins.[556]

Future studies in yeast will include a detailed characterization of the *vps* genes and their encoded products. The use of *in vitro* reconstitution assays for vacular protein sorting[557] should aid in revealing the precise roles of these proteins in the sorting process (e.g., in receptor-mediated recognition/sorting, vesicularization and vesicle targeting, and fusion events). A clear understanding of these roles should in turn provide insight into how the various sorting components interact as well as the more general roles of protein phosphorylation and GTPases in intracellular protein sorting processes. Although yeast has not been a suitable model system for identification of plant vacuolar targeting signals, it may be an appropriate model system to identify novel mechanisms of protein retention within the plant ER.[489] A yeast system would be particularly valuable to study targeting of plant proteins, given its extensive set of secretion and BiP mutants. Moreover, transformation techniques for cereals are currently limited, and long periods of time are required to obtain transgenic cereal plants.[489]

6. Identifying Plant Vacuolar Targeting Signals

a. Use of Transgenic Yeast as the Heterologous Host System

Because the plant vacuolar protein PHA is correctly processed and sorted to the yeast cell vacuole,[521] transgenic yeast has been used as a model system to attempt to define the vacuolar targeting signal on this protein.[558] A PHA fusion protein containing 43 amino-terminal residues of the mature protein, together with the signal peptide, is sufficient to redirect the secreted form of yeast invertase to the yeast vacuolar compartment. Deletion analysis further localized the vacuolar sorting domain to an amino-terminal portion of mature PHA, between amino acids 14 and 23.[558] Interestingly, this domain contains a yeast-like vacuolar targeting (tetrapeptide) sequence, $LQRD_{21}$, reminiscent of the $LQRP_{26}$ sequence on CPY, and conserved to some degree in other lectin proteins of legumes.[17] Site-directed mutagenesis to effect amino acid changes within this tetrapeptide sequence in PHA-invertase fusion proteins has demonstrated the importance of this short domain in the vacuolar sorting reaction in yeast. In particular, exchanging the aspartate at position 21, which introduces a site for addition of a glycan into the sequence, results in considerable secretion of invertase activity (e.g., 64%). However, the effect of similar mutations within this short domain in full-length PHA does not significantly affect targeting of the protein to the vacuole, indicating that there is additional vacuolar targeting information in PHA.[17,558] Thus, a second independent signal present towards the middle of the polypeptide (i.e., carboxy-terminal to the first domain identified) may also be essential for correct sorting in yeast cells, notably similar to the requirements for PrA and PrB (see earlier discussion).[17]

Perhaps more important, however, is the observation that the PHA-invertase fusion proteins that direct transport to the yeast cell vacuole are not targeted successfully to vacuoles in *A. thaliana*. Therefore, the sorting determinant that contains sufficient information for vacuolar targeting in yeast lacks the necessary information for efficient targeting in plants, suggesting that vacuolar sorting signals in these two organisms are dissimilar, perhaps in the extent to which other determinants in the mature protein are required for their receptor-mediated recognition.[17] Further studies on various PHA-invertase chimeric constructs expressed transiently in plant protoplasts reveal that vacuolar sorting information is contained within an internal domain of PHA that is predicted to be exposed at the surface of the folded molecule.[559] The internal domain consists of 30 amino acids (amino acids 84 to 113 in mature PHA) and is capable of directing 50% of the reporter protein to the plant vacuole. It does not appear to share any sequence homology with the vacuolar targeting signals identified on other plant proteins (see discussion below).

Fusion proteins of pea legumin and yeast invertase indicate that targeting information (for the yeast vacuole) is contained in both the amino-terminal and carboxy-terminal portions of the legumin protein.[560] The vacuolar sorting signals of some yeast and possibly certain plant proteins (e.g., legumin of field bean)[560] may be composed of regions on the surface of the protein that are commonly termed 'signal patches' (Figure 2). Unlike signal peptides, signal patches will, in general, be formed from noncontiguous regions of the polypeptide chain that are brought together during protein folding; thus, they are conformation dependent.[16] A dependence on signal patches for correct sorting would obviously contribute to the difficulty of defining these domains experimentally, particularly via engineered (chimeric or deletion) proteins that contain (or lack) only continguous amino acid sequences (Figure 3). Although we presume it to be the case, we do not yet know with certainty whether the three-dimensional conformation of proteins is precisely the same in the heterologous yeast vs. plant-host cells; there may be subtle differences, such that different protein determinants or features are more (or less) accessible for receptor-mediated recognition in these two systems. However, the sorting determinants per se that are critical for plant vs. yeast vacuolar targeting appear to be different.[488,561,562] For example, as will be discussed in the next section, a carboxy-terminal propeptide (CTPP) on barley lectin is a vacuolar targeting signal in plants, being both necessary and sufficient for vacuolar localization in transgenic tobacco. Barley lectin domains redirect the normally secreted reporter protein invertase, for sequestration in yeast, but they do so in a manner independent of the carboxy-terminal propeptide.[561] Invertase with only the plant protein carboxy-terminal propeptide is secreted in yeast. Conversely, two fusion proteins consisting of invertase linked to barley lectin containing its carboxy-terminal propeptide or to

barley lectin lacking this amino acid-stretch are both retained in yeast cells.[561] Similar results have been obtained with another plant protein, sporamin, in which the plant vacuolar targeting signal is a N-terminal propeptide.[562] Thus, none of the three types of plant vacuolar-targeting signals identified so far (i.e., an internal domain, a N-terminal propeptide, or a C-terminal propeptide) are recognized in yeast. Moreover, in all cases, another cryptic signal was found, confirming the lack of conservation of certain components of the vacuolar targeting machinery between plants and yeast.

b. Use of Transgenic Plants as the Heterologous Host System

Several studies have demonstrated that plant vacuolar proteins are correctly targeted in other plant hosts (reviewed in Reference 17). In general, the vacuolar targeting signals on these proteins are recognized with a high degree of fidelity, regardless of the species, cell type, or organ in which expression is directed. However, transport efficiency may be variable and has not been systematically determined; likewise, there may be differences between vegetative and seed tissues (see later discussion). Progress has been made toward identifying the molecular mechanisms regulating the vacuolar sorting of Gramineae lectins.[563-566] Barley lectin is synthesized as a preproprotein with a glycosylated CTPP that is removed just prior to, or concomitant with, deposition of the protein in vacuoles.[567] The intact protein is correctly assembled, processed, and targeted to the vacuole in heterologous tobacco host cells.[82] Expression of a mutant form of the lectin gene, in which the region encoding the short pro-domain is deleted, results in missorting and secretion of the protein via the bulk-flow transport pathway.[563] The CTPP on the lectin is also sufficient for vacuolar targeting; when the corresponding DNA sequence is fused to a gene encoding a secreted reporter protein (cucumber chitinase), the resultant fusion protein is redirected to the vacuole in transgenic tobacco with 70 to 75% efficiency.[464,490] Other Gramineae lectins such as wheat germ agglutinin and rice lectin contain similar proteolytically processed C-terminal domains,[568] and these probably serve the same function. Sporamin (a vacuolar storage protein in tuberous roots of sweet potato) undergoes a pattern of proteolytic processing that is similar to that of the cereal lectins. This protein is synthesized as a preproprotein with a short amino-terminal propeptide (NTPP) domain that undergoes cleavage in a posttranslational manner, probably in the vacuole.[569] Studies of the fate of sporamin gene constructs in transgenic tobacco show a dependence on the amino-terminal prodomain for correct vacuolar targeting, similar to that demonstrated for the carboxy-terminal prodomain of barley lectin.[570] Thus, in these two vacuolar proteins (which have a similar pattern of precursor synthesis and posttranslational proteolytic processing) the prodomains appear to contain information that is essential and sufficient for vacuolar sorting.

Subsequent studies analyzing the functional elements of the barley lectin C-terminal prodomain suggest that no specific amino acids are involved; many different alterations and deletions were tolerated by the targeting machinery, although short hydrophobic amino acid stretches seemed important.[566] As few as three amino acids of the CTPP are sufficient for the correct targeting of barley lectin to the plant vacuole. Neither charge nor glycosylation of the prodomain are necessary for targeting. The predicted secondary structure (i.e., an amphipathic α-helix)[571] is also not required for recognition by the vacuolar sorting apparatus; however, correct three-dimensional presentation of the domain appears to be essential.[564,565] Addition of two glycine residues after the terminal glutamic acid (Table 10) or the addition of an N-linked glycosylation site, four amino acids from the carboxy-terminus, causes secretion of barley lectin from tobacco cells.[566] Thus, the carboxy-terminus is clearly the site of recognition by the sorting machinery and the addition of glycine residues or a bulky glycan at this site significantly alters delivery of the protein to the vacuole.[488] Comparison of the propeptide sequence of sporamin to other propeptide sequences (e.g., on barley aleurain and potato cathepsin D inhibitor) reveals a common short region of hydrophobic amino acids (NPIRLP) with a hydrophilic residue, Arg, in the center (Table 10); Asn (N) and Ile (I) are conserved, and Pro (P), Arg (R), and Leu (L) can be substituted.[492,572] Progress is being made toward determining the critical residues in this region that are necessary and sufficient for vacuolar sorting.[572,573] Conserved amino acids in the N-terminal part of the propeptide of sporamin ($N^{26}PIRL^{30}$) (Table 10) may constitute the core of the vacuolar-sorting determinant; both the side-chain structures of the conserved residues and the higher-order structure of the polypeptide backbone in this region are likely recognized by the vacuolar sorting machinery.[573]

Propeptides of vacuolar proteins do not necessarily contain targeting information. A short C-terminal segment of a Brazil nut 2S albumin is sufficient for targeting to the vacuole;[574] conversely, none of the three propeptide segments of the *Arabidopsis* 2S albumin storage protein (which undergo proteolytic removal) are involved in vacuolar localization.[575]

Recent studies with some of the pathogenesis-related proteins of tobacco (e.g., chitinase, β-glucanase) have also led to the identification of the vacuolar sorting domains on these proteins. Homologous extracellular and vacuolar forms of these hydrolytic enzymes exist; acidic forms are generally extracellular, whereas their basic counterparts (likely encoded by different gene products) are vacuolar.[26,576,577] A basic chitinase of tobacco is synthesized as a higher molecular weight precursor, with three domains that are not present on the acidic form (viz., an insertion in the middle of the polypeptide and short amino-terminal and carboxy-terminal domains).[25] The carboxy-terminal tail of the basic tobacco chitinase appears to have significant vacuolar targeting information;[578] deletion of a carboxy-terminal heptapeptide from the basic enzyme leads to secretion of the mutant chitinase from transgenic tobacco cells. Conversely, a fusion protein (containing the carboxy-terminal domain of basic tobacco chitinase linked to an acidic [extracellular] cucumber chitinase) is retained to a substantial degree (i.e., 50%) in transgenic tobacco cells and is sufficient for vacuolar localization. Likewise, the targeting information on the vacuolar antifungal tobacco enzyme AP24 resides in its short carboxy-terminal propeptide that is removed concomittantly, or subsequent to, transport to the plant vacuole.[579]

A comparison of the C-terminal extensions of the lectins and vacuolar hydrolases (tobacco chitinase and β-glucanase) reveals no amino acid identities (Table 10); however, a common feature is an abundance of hydrophobic amino acids, which may be important for recognition by sorting machinery.[490] Sequence changes in the C-terminal vacuolar targeting peptide of tobacco chitinase lead to a gradual transition from vacuolar retention to secretion, suggesting that (at least for some proteins) the vacuolar sorting system has low specificity for the primary sequence of the targeting domain.[580]

Aleurain, a vacuolar thiol protease in barley aleurone layer cells, is made as a 42-kDa proenzyme (proaleurain). Aleurain is proteolytically processed into its mature form by the removal of a N-terminal propeptide[338] whose amino acid sequence shares identities with the sporamin prodomain (Table 10).[83] Two steps are required to form the mature 32-kDa aleurain; the first yields a 33-kDa intermediate; subsequent trimming results in the gradual loss of 1 kDa. Two homologous thiol proteases, aleurain and EP-B, each of which have N-terminal propeptides of about 110 amino acids, are simultaneously expressed in aleurone layer cells, but have different destinations (vacuolar vs. extracellular, respectively). Toward identifying the vacuolar sorting signal on aleurain, chimeric proteins resulting from switching prosequences from the two proteins have been constructed and their fate (i.e., subcellular localization) examined in heterologous host plant cells.[178,581] Substitution of the propeptide of EP-B with the N-terminal propeptide of aleurain (containing the amino acids SSSSFADSNPIR) results in redirection of about 50% of EP-B to the vacuole.[178] Shorter sequences of this domain (SSSSFADS and SNPIR) are also able to target pro-EP-B to the vacuole, albeit with much lower efficiencies compared with the combined sequence. Efficient vacuolar sorting of aleurain may, therefore, be mediated by the combined action of small contiguous determinants.[178,581]

Thus, significant insight into vacuolar sorting may be derived from comparisons of amino acid sequences of homologous extracellular and vacu-

TABLE 10
Vacuolar Sorting Signals in the N-Terminal and C-Terminal Propeptides of Plant Vacuolar Proteins

Vacuolar protein	Location of propeptide	Targeting signal
Sweet potato sporamin	N-terminal	+ H S R F N P I R L P T - - -
Barley aleurain	N-terminal	+ S S S S P A D S N P I R P V T D R A A S T - - -

Tobacco chitinase A	C-terminal	- - g n G L L V D T M -

Note: In the amino acid sequence of the propeptide, hydrophobic amino acids are indicated by bold letters, and the positive and negative charges in the polypeptides are indicates by + and –, respectively. ∇ indicates the cleavage site of the CTPP. The N-linked glycan (Y) is attached to an Asn residue in the barley lectin CTPP. The exact N-terminal amino acids of prosporamin and proaleurain in tobacco cells are not known. The NPIR motif in the N-terminal propeptides and the hydrophobic/acidic motif in the CTPPs are indicated by the underlines (solid underlines and broken underlines, respectively).

Based on Nakamura, K., and Matsuoka, K., *Plant Physiol.*, 101, 1, 1993. With permission from the American Society of Plant Physiologists.

olar proteins.[17] Subsequent studies utilizing this information can then be geared to identifying those domains that are both necessary and sufficient for correct targeting of the vacuolar form.

In legume root nodules, proteins of the peribacteroid fluid are targeted through the endomembrane system to the peribacteroid membrane. Although the mechanisms for targeting of peribacteroid membrane proteins are presently unknown, they may be various as indicated by the nature of nodulin-26 vs. nodulin-24.[582,583] A contributing factor to targeting of these nodulin proteins may be that the peribacteroid membrane is a mosaic, having properties common to both the plasma membrane and the vacuole.[417]

Although there are exceptions, it is noteworthy to mention here that identification of vacuolar targeting signals on seed storage proteins may not be successful by analyzing the fate (i.e., subcellular localization) of engineered proteins in plant vegetative tissues. This appears to be the case for vicilin of pea seeds.[584] Subcellular localization studies of vicilin deletion mutant and chimeric proteins in leaf cells indicated possible participation of both N-terminal and C-terminal regions of the mature protein in vacuolar targeting; both a 121-amino acid N-terminal deletion mutant and a 69 amino acid C-terminal deletion mutant failed to accumulate in the leaf vacuole. However, protein degradation in the leaf vacuole and disrupted assembly were likely to be important factors contributing to the low levels of deletion mutant proteins detected in this compartment. Highly specific proteolytic processing was exhibited by the same mutant proteins synthesized in tobacco seed that may reflect significant correct targeting to the storage vacuole/protein body in seed tissues. Interestingly, expression of the gene encoding the α-subunit of soybean β-conglycinin in transgenic petunia (under control of the cauliflower mosaic virus 35S promoter) leads not only to differential levels of protein accumulation but also to differential processing and transport in the leaf vs. the seed. For example, the two major products in seeds are 76 kDa (the intact α′ subunit) and 55 kDa (a breakdown polypeptide of the α′ subunit) that accumulate only in protein storage vacuoles (protein bodies). In contrast, a polypeptide of 80 kDa, the predicted size of the α′ precursor, and a 53 kDa breakdown polypeptide are found in leaves and other non-seed tissues.[585] Moreover, in the non-seed tissues, these products were localized within a microsomal membrane fraction containing ER and Golgi. On a cautionary note, this may simply indicate that the products are unstable in the leaf vacuole, and proteins in the ER and Golgi represent the small amounts of protein in transit to the vacuole. In somatic embryos of alfalfa (derived from vegetative tissues), there is mistargeting of 2S albumin storage proteins (normally vacuolar proteins) that localize to the cytosol.[586] Thus, it appears that problems related to protein stability and possible loss of fidelity of targeting make the vegetative tissues inappropriate model systems to identify the vacuolar targeting signals on some seed storage proteins.

c. Targeting of Membrane Proteins to the Tonoplast

Some progress has been made toward identifying the targeting signals of tonoplast proteins in plants.[180,203] As mentioned earlier, in bean seeds, α-TIP is synthesized on the rough ER, and its transport to the tonoplast is mediated by the secretory system. The C-terminal 48 amino acids of α-TIP, which include the sixth membrane-spanning domain and the cytoplasmic tail, can redirect a soluble reporter protein to the tonoplast in tobacco cells. A mutant form of α-TIP (in which the C-terminal cytoplasmic tail is deleted) is still targeted to the tonoplast. The C-terminal transmembrane domain may contain the information for transport to the tonoplast; however, deletion of the sixth membrane-spanning region results in an unstable protein.[203] Recent work in yeast suggests that targeting of membrane proteins to the vacuole occurs via a default mechanism.[533,587] For example, removal of a positive targeting signal from a Golgi-associated membrane protein (KEX1) results in its mislocalization and transport to the vacuolar membrane.[587] In plants, work with the transport inhibitors monensin and brefeldin suggests that soluble proteins of the vacuole (e.g., PHA) and membrane proteins (e.g., α-TIP) reach their vacuolar destinations by different paths.[180] As mentioned earlier, in some eukaryotic sys-

tems, brefeldin A prevents anterograde vesicle transport between the ER and Golgi complex. Specifically, it prevents the assembly of coatomers due to its inhibition of the GTP-dependent interaction of the ADP-ribosylation factor with the Golgi membrane.[588,589] Monensin, on the other hand, inhibits correct sorting in the TGN by disrupting the proton gradient across the membrane. Both inhibitors prevent vacuolar transport of PHA, but are ineffective in blocking arrival of α-TIP in the tonoplast.[180] Although these results are indicative that transport to the plant tonoplast represents a default pathway, further work is necessary to confirm this model, including a determination of the unique features of the plant Golgi complex as well as the precise effects of monensin and brefeldin on plant secretory pathway functions.

d. Other Components of the Plant Vacuolar Targeting Machinery: A Search for Receptors

To fully understand plant vacuolar targeting mechanisms, it will be necessary to undertake a detailed characterization of the sorting signals from various proteins with different functional and structural characteristics. The above studies make it clear that the sorting signals on plant vacuolar proteins are various and include internal domains, 'signal patches,' and prodomains, the latter removed when vacuolar transport is completed (Figure 28). The identification of specific sequences required for vacuolar targeting has initiated a search for receptors mediating the recognition of those signals.[590,591] A comparison of targeting sequences on different vacuolar proteins

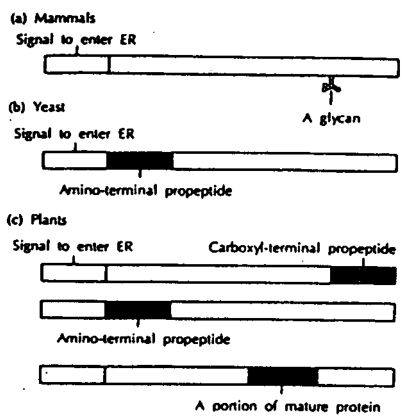

FIGURE 28. A summary of targeting signals of vacuolar/lysosomal proteins in eukaryotes. (c) Shows three different regions in which the vacuolar sorting and targeting information occur in plant proteins: in the cleaved carboxy-terminal or amino-terminal propeptide, or internally within the mature protein. The signal peptide for insertion in the ER is shown for each protein. See Chrispeels and Raikhel.[490] See also Holwerda et al.,[178] Bednarek and Raikhel,[83] and Nakamura and Matsuoka.[492] (From Gal, S. and Raikhel, N. V., *Curr. Opin. Cell Biol.*, 5, 636, 1993. With permission from Current Biology.)

has revealed little amino acid similarity; thus, it is pertinent to ask whether different classes of targeting signals compete for the same receptor[592] (reviewed in Reference 488). Tobacco plants synthesizing barley lectin (containing a CTPP) were crossed with those expressing sporamin (having an NTPP), and the progeny was analyzed. Competition between these two proteins for the same receptor was expected to lead to secretion of one of the proteins; however, both proteins were correctly processed and localized to the same vacuoles.[592] Thus, the carboxy-terminal and NTPPs are equally recognized by the vacuolar protein-sorting machinery indicating the existence of multiple sorting receptors or a broad-specificity sorting mechanism that is not easily saturated.

An integral membrane protein of ~80 kDa (BP-80) has been identified in clathrin-coated vesicles of developing pea cotyledons. The protein binds specifically (at neutral pH) to the N-terminal targeting signal of proaleurain (bound to a column) and dissociates from its ligand when the pH is lowered to 4. The NTPP of sporamin competes (weakly) for binding of the putative receptor protein; a mutant form of this NTPP does not. Likewise, endopeptidase-B (EP-B), a homologous, secreted thiol protease, also does not exhibit an interaction with the 80-kDa protein. The transmembrane orientation of the protein is also indicative of a receptor function; the carboxy-terminus is exposed to the cytoplasm, whereas the binding domain is located in the N-terminal luminal portion of the protein.[591] At present there is no direct functional evidence that BP-80 acts as a vacuolar receptor. However, both pea and *Arabidopsis* have multiple genes for proteins closely related to BP-80 and similar genes are expressed in maize and rice (reviewed in Reference 591a; see references therein). Further characterization of this putative plant vacuolar targeting receptor will be awaited with interest. Another future goal is the isolation of plant mutants having specific defects in vacuolar protein targeting (similar to those in yeast); these will be valuable for identifying other components integral to the transport and sorting machinery.[330] As will be discussed in the next section, this basic research will be of value for more applied studies geared toward the genetic engineering of plants with improved traits.

VI. APPLICATIONS TO GENETIC ENGINEERING: MAXIMIZING LEVELS OF GENE EXPRESSION IN FOREIGN PLANT HOSTS

Subsequent to the advent of genetic engineering of plants, there has been an ongoing thrust toward refinement of the techniques for gene isolation and manipulation, plant host transformation, and efficient regeneration of whole plants from single transformed cells. Current attention is focused on using the technology to define or elucidate regulatory mechanisms of plant gene expression and as a means of introducing agronomically useful traits or characters into crop plants. One major goal is to engineer seed crops for greater nutritional value by introducing storage proteins modified to contain a more optimal balance of the essential amino acids (i.e., those amino acids that cannot be synthesized by animals and hence, must be supplied in their diet). Another related goal (particularly important to the economy of Australia and New Zealand) is to obtain high levels of accumulation of certain sulfur-rich, rumen-resistant storage proteins within the leaves of pasture plants (e.g., lucerne and subclover), with the aim of increasing wool growth in sheep.[156,157] Other desirable traits that researchers are presently focused on include the engineering of insect, disease, and herbicide resistance in crop plants, as well as the production of medicinally important substances in plants.

To be of agronomic value (particularly in relation to enhanced nutritive value), levels of the foreign protein must accumulate to significant levels in the host plant (e.g., to about 1 to 10% of the total cellular protein); it may also be desirable to target protein accumulation into a suitable subcellular compartment. The former objective is particularly challenging because levels of foreign proteins in transgenic plants (particularly within vegetative tissues) are generally low, although there are notable exceptions.[593-596] Thus, concerted efforts are being made to enhance gene transcription and mRNA stability and translatability to achieve high protein levels. Such attempts generally have been successful,[156,157] yet in some instances have led to insufficient increases in foreign protein accumulation to be of economic consequence. More recently, a novel strategy has

been the "mis-" or "retargeting" of proteins into different subcellular compartments to improve the stability of foreign proteins in transgenic plants.

A. Enhancing Protein Stability in Transgenic Host Plants

It has become evident that a lack of stability of the introduced protein in the foreign host environment is a major obstacle that must be overcome to obtain high levels of protein accumulation. Protein instability may be due to structural constraints (e.g., as a consequence of mixed or additional coding sequences); it may also arise as a consequence of the subcellular localization of the protein in the foreign host environment. Thus, success in achieving high protein levels in transgenic host plants will likely depend on a close scrutiny of targeting signals, as well as the structural features of proteins that allow for their stable accumulation in cells. The importance of these factors is underscored by studies attempting to introduce storage proteins that have been structurally modified to enhance their nutritional quality.[311,597] For example, a high-methionine β-phaseolin gene (modified to contain codons for 15 additional amino acids, including six methionine residues), yielded very low levels of accumulation in transgenic tobacco seeds, as a consequence of increased protein degradation. The majority of the modified protein was degraded within the seed vacuole.[311,312] Similarly, a gene with a modified CAT (chloramphenicol acetyl transferase) coding region (in which a 292-base-pair coding sequence encoding 80% essential amino acids was inserted) gave very low levels of protein in transgenic potato tubers.[597]

Knowledge of the rules that relate amino acid sequence to protein structure is not only fundamental to our understanding of such important biological processes as protein folding and the achievement of a functional three-dimensional structure, but also will be essential to any attempts to modify the nutritional quality of proteins. Tolerance to amino acid substitutions in relation to protein structure (and hence stability) and function is just beginning to be elucidated (reviewed in References 598 through 601). Proteins appear to vary widely in their tolerance to amino acid changes. Zeins, the prolamin storage proteins of maize, lack the essential amino acids lysine and tryptophan. In contrast to the failed attempts to modify phaseolin and CAT genes (noted above), modifications to a zein gene to introduce lysine and tryptophan codons (at several positions) do not affect the stability of the zein protein when the mRNAs are translated in *Xenopus* oocytes.[602] This result is promising in relation to the possibility of creating high-lysine corn by genetic engineering; stability of modified zein proteins in transgenic host plants now requires testing. Presumably, this protein can tolerate even severe modifications; a gross alteration (in which a 450 base pair open reading frame from a simian virus 40 coat protein was inserted into the coding region) did not affect zein protein stability, although its ability to aggregate and form protein bodies was affected.[602]

In general, seed storage proteins are significantly more stable in the seed of a foreign plant host than in the leaf, a factor that has impeded attempts to achieve high levels of protein accumulation in vegetative organs.[156,157,603,604] The low levels of accumulation of seed storage proteins observed in the transgenic host leaves, when compared with the seed,[585,603–605] may result from the continuous breakdown of the proteins in the protease-rich vacuoles of the leaves.[156] For example, despite similar levels of β-conglycinin mRNA in the leaves and seeds of transgenic petunia (utilizing a constitutive viral promoter to drive expression), the leaf cell environment yields a much lower level of protein accumulation.[585,604] A similar phenomenon occurs when pea vicilin is expressed in the leaves and seeds of transgenic tobacco.[156,584,605] Much higher levels of vicilin are detected in younger tissues (leaves) than in older ones, which is indicative that the rate of breakdown exceeds the rate of synthesis in these older tissues.[605] In many cases, it appears that the vacuolar targeting signals of seed storage proteins are recognized and processed correctly in the leaf cell environment because correct vacuolar transport of the protein occurs with a high degree of fidelity; however, there are important exceptions. Proteolytic processing of storage proteins commonly occurs upon their arrival in the vacuole. Differential proteolytic processing of storage proteins (e.g., β-conglycinin, vicilin) yields polypeptides of variable length in seed vs. nonseed tissues.[585,604,605] Analyses of proteolytic processing of vicilin deletion mutant proteins also reveal significant differences in leaf vs. seed tissues of the tobacco host (Figure 29); presently, it is not clear whether this reflects different subcellular sites of accumulation in the two tissues or whether there are differences in the substrate specificities of resident endoproteases.[584] The relationship between the differential processing of storage proteins and

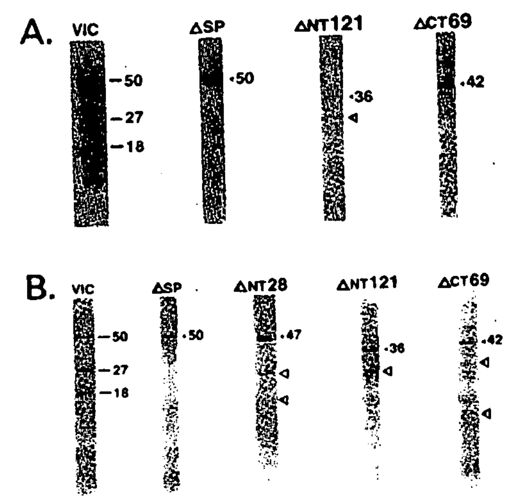

FIGURE 29. Proteolytic processing of pea vicilin deletion mutant proteins synthesized in the leaf and seed of transgenic tobacco. When expressed in transgenic tobacco seed, unmodified pea vicilin undergoes partial proteolytic processing yielding major polypeptide products of 50 (unprocessed), 27, and 18 kDa, indicative of a preferential usage of one of the two cleavage sites (P_1). In-frame deletions were made within the region of the vicilin gene, encoding mature protein, to eliminate the N-terminal 28 and 121 amino acids and the C-terminal 69 residues, while maintaining an intact signal peptide (ΔNT28, ΔNT121, and ΔCT69, respectively). (A) Mutant proteins synthesized in transgenic leaves. (B) Mutant proteins synthesized in transgenic seed. Open arrows indicate processed polypepides. All deletion mutant proteins undergo some normal proteolytic processing in the seed; the C-terminal deletion mutant remains unprocessed in the leaf. A modified vicilin gene, in which the DNA sequence corresponding to the signal peptide was removed (ΔSP), results in a polypeptide of 50 kDa in tobacco leaf and seed; none of the normal proteolytic cleavage products characteristic of expression of an unmodified vicilin gene are obtained (VIC: unmodified or intact vicilin protein synthesized in leaf or seed). (From Kermode, A. R., Fisher, S. A., Polishchuk, E., Wandelt, C., Spencer, D., and Higgins, T. J. V., *Planta*, 197, 501, 1995. With permission from Springer-Verlag, New York.)

protein instability due to proteolytic breakdown may need to be understood before the problem of low protein amounts in non-seed tissues can be fully addressed.

Because an instability of storage proteins in the leaf may, in part, be due to their (correct) vacuolar localization, one novel approach to overcome this problem is to "mistarget" proteins into subcellular compartments other than the vacuole.[156,157] Removal of the signal peptide sequence of a protein should abolish its transport to the leaf cell vacuole; entry into the ER lumen, and hence, the secretory pathway, is denied. Indeed, vicilin accumulation in the leaves of transgenic tobacco is increased by about fivefold when the DNA sequence corresponding to the signal peptide sequence is removed.[157] This modified vicilin gene results in a polypeptide of 50 kDa; none of the normal proteolytic processing products (characteristic of expression of an unmodified vicilin gene) are obtained, intimating that vacuolar transport is abolished. The fivefold increase in protein level is obtained from a level of vicilin mRNA that is lower than that obtained with the unmodified gene. Thus, the vicilin protein appears to be more stable as a consequence of its cytosolic localization.

Expression of a vicilin gene modified to encode an ER-retention signal (SEKDEL) at the carboxy-terminus of the protein results in a 100-fold increase in vicilin accumulation in the leaves of transgenic tobacco and alfalfa when compared with its unmodified counterpart.[156,157] This increase in protein is obtained without any change in vicilin mRNA level. Enhanced stability of the modified protein (which achieved a level of 2.5% of the total tobacco soluble leaf protein) may occur as a consequence of its new subcellular localization (i.e., predominantly in the ER), where, presumably, it receives some protection from proteolysis. Alternatively, there may be structural changes to vicilin as a consequence of its new carboxy-terminus that somehow render the protein more stable. Thus, targeting to a new subcellular locale may not be the sole factor involved in the enhanced protein stability. Manipulating the subcellular targeting of pea albumin 1 to increase accumulation of the protein in leaves of transgenic white clover and tobacco indicates that the endomembrane system is a relatively stable environment compared with the cytoplasm or chloroplast.[606]

The targeting and stability of engineered zeins in transgenic yeast cells have been examined.[607] Unmodified zein is targeted to (and accumulates within) the ER lumen in transformed yeast cells, as predicted for this maize storage protein. However, a truncated zein protein (in which the signal peptide and the first 36 amino acids of the mature protein are deleted) is synthesized in the cytoplasm and massively accumulates in the mitochondria, where it aggregates in protein body-like structures, similar to those present in maize endosperm cells. Thus, there appear to be distinct or separate domains of the zein polypeptide that, on the one hand, are responsible for membrane targeting; others may be responsible for the stability and aggregation of this storage protein.[607]

B. Enhancing Posttranslational Processes: Folding and Oligomer Assembly

The design of polypeptide sequences with a functional and stable three-dimensional conformation is impeded by our limited knowledge of the rules that govern protein folding and oligomer assembly and how these processes relate to a protein's ultimate stability in cells. Strategies must be developed to predict and avoid degradation of recombinant proteins in heterologous host cells, particularly in cases where these proteins contain sequences that render them sensitive to proteases, specifically targeting them for degradation.[608,609] A novel way to overcome some of the fundamental problems associated with protein design may be the construction of proteins *de novo* with unnatural (but highly stable) chain architectures by making use of the tools of synthetic chemistry (reviewed in Reference 610). It may also be possible to design modified storage proteins of desirable composition (e.g., rich in the sulfur-containing amino acid cysteine) that are stable and undergo correct folding and assembly in a manner reminiscent of natural (unmodified) seed storage proteins. Multiple cystine residues in a newly designed protein molecule may play an important role in stabilizing the protein; these have been shown to significantly stabilize the native structure of a protein,[611] and may also render proteins resistant to proteolysis.[612] Transient associations of seed storage proteins with molecular chaperones resident in the ER may also be a prerequisite for their correct folding and oligomeric assembly in foreign host cells. This may be achieved by ER-resident proteins that are endogenous in the foreign host cells, or it may require the introduction of genes encoding such "ER-helper" proteins from the donor genome. Glycosylation may play a general role in protein stability, primarily because of its promotive effect on protein folding; increasing the number of glycosylation sites (and their strategic positioning within a designer protein, for example, by site-directed mutagenesis) may increase both transport efficiency and stability.

A major system for selective protein degradation is the ubiquitin pathway in which proteins are committed to degradation by their ligation to ubiquitin as a multiubiquitin chain (reviewed in References 613 and 614). Although not yet tested in plant host systems, ubiquitin may be useful as a means of stabilizing proteins within heterologous hosts.[614–616] Interestingly, fusion of ubiquitin (by recombinant DNA techniques) to the amino-terminus of a protein can prevent it from degradation in yeast,[617] and results in increased accumulation, up to several hundredfold. The precise mechanism(s) responsible for such a dramatic increase in expression level is not clear. Ubiquitin may protect the amino-terminus of the fusion protein from proteolysis; alternatively, it may somehow guide the protein into a new compartment where it receives greater protection from proteases. Enhanced translation of the fusion protein may also have contributed to the increased expression. It will be interesting to determine whether a similar fusion of the ubiquitin gene to the coding region of a storage protein gene yields increased stability of the product in heterologous plant host cells.

VII. TARGETING OF PROTEINS TO THE NUCLEUS

A. Nuclear Structure and Components

Most of the DNA of eukaryotic cells is sequestered in the nucleus, an organelle delimited by two concentric membranes: the outer and inner nuclear membranes that together comprise the nuclear envelope (Figure 30). The outer nuclear membrane closely resembles the membrane of the rough ER, and like the latter, is studded with ribosomes engaged in protein synthesis. Proteins made on these ribosomes are transported into the space between the outer and inner nuclear membranes (the perinuclear space), which is continuous with the ER lumen.[94] The nucleus derives its mechanical strength from two networks of cytoskeletal elements; there is a thin meshwork of intermediate filaments lining the inner surface of the inner nuclear membrane (the nuclear lamina) and a less organized system of intermediate filaments surrounding the outer nuclear membrane. Plant cells also contain a nuclear lamina; its biochemical composition in pea nuclei appears to be similar to that in vertebrate and invertebrate animal cells, consisting of an array of 1 to 3 extrinsic membrane proteins, lamins A, B, and C and similar enzyme activities (nucleoside triphosphatase activity, derived from proteolysis from lamin A/C molecules in the nuclear scaffolding).[619,620] Specific proteins of the inner nuclear membrane act as binding sites for the nuclear lamina that supports it.

Proper functioning of the eukaryotic cell requires extensive bidirectional macromolecular traffic between the nucleoplasm and the cytoplasm. Nuclear import and export are highly specific processes, despite the dynamic nature of the nuclear envelope that dissolves during mitosis and is reconstructed after the completion of cell division, necessitating the reentry of nuclear proteins. The specificity of nuclear trafficking is due, in part, to the perforation of the nuclear envelope by nuclear pores (Figure 30). Each pore is formed by a large, elaborate structure known as the nuclear pore complex that traverses the envelope, bringing the lipid bilayers of the two membranes together around the margins of the pore. The complex is thought to be composed of more than 100 different proteins arranged with a striking octagonal symmetry; its estimated molecular mass is 125 million Da. Bidirectional transport is allowed through the pore complexes that contain one or more open aqueous channels, estimated by experimental means to have an effective size of 9 nm in diameter and 15 nm long — only a frac-

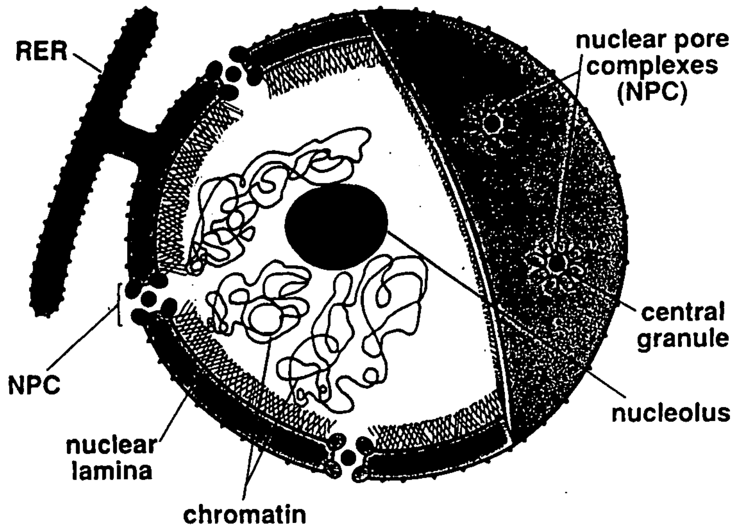

FIGURE 30. Schematic representation of the nucleus. (From Raikhel, N. V., *Plant Physiol.*, 100, 1627, 1992. With permission from the American Society of Plant Physiologists.)

tion of the total pore volume. Thus, the pore complex contains a pathway for free diffusion equivalent to a water-filled channel about 9 × 15 nm, such that molecules smaller than this size can passively diffuse (although exceptions exist). Because many cellular proteins are too large to pass by diffusion through the nuclear pores, the nuclear envelope allows the nuclear compartment and the cytosol to maintain different complements of proteins.

B. Mechanisms of Nuclear Targeting

1. Macromolecular Transport Across the Nuclear Envelope

Due to the presence of nuclear pores, transport into the nucleus is fundamentally different from that into other organelles, where proteins pass directly through the membrane. Included among large proteins selectively imported into the nuclear compartment from the cytosol where they are made are the histones, DNA and RNA polymerases, gene regulatory proteins, and RNA processing proteins. At the same time, tRNAs and mRNAs are synthesized in the nuclear compartment and then exported to the cytosol (Figure 31). Similar to the import process, the export process is highly selective; mRNAs, for example, are exported only after they have been correctly modified by RNA-processing reactions in the nucleus (e.g., by capping, polyadenylation, and splicing). Although many proteins remain within the nucleus after their import, others undergo shuttling (i.e., are continuously exported from the nucleus to the cytoplasm and are reimported into the nucleus). Although the significance of the shuttling process is not entirely clear, proteins that undergo this event have been identified in a range of eukaryotic cell types and include nucleolar proteins, steroid hormone receptors, heat-shock proteins, heterogeneous nuclear ribonucleoprotein (hnRNP) proteins, and the U1 small nuclear RNP (snRNP)-specific protein U1A. In some cases, the transport process is complex: ribosomal proteins, for example, are made in the cytosol, imported into the nucleus — where they assemble with newly made ribosomal RNA into particles — and then are exported again to the cytosol as part of a ribosomal subunit; each of these steps involves selective transport across the nuclear envelope.[94] In some cases, nuclear import of proteins must be strictly regulated by developmental or environmental cues, as in the case of gene regulatory proteins, which exert their control only at certain times or only under certain conditions. Plants, which must be more adaptive than animals to cope with changing environmental conditions, have likely evolved highly efficient regulatory mechanisms.[618]

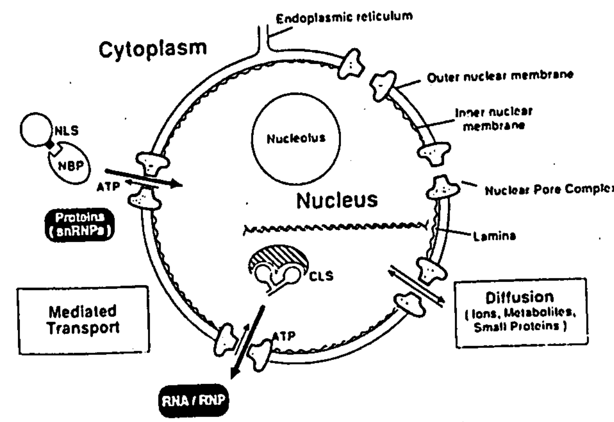

FIGURE 31. Nuclear import and export. See text for details. NLS, nuclear localization signal; NBP, NLS-binding protein; CLS, cytoplasmic localization signal. (From Nigg, E. A., Baeuerle, P. A., and Lührmann, R., *Cell*, 66, 15, 1991. With permission from Cell Press.)

2. Protein Import in Animal and Yeast Cells

When proteins are extracted from the nucleus and microinjected back into the cytosol of animal cells, even the very large ones are efficiently accumulated in the nucleus. The selectivity of nuclear import of proteins in all eukaryotic cells is due to the presence of a nuclear localization signal (NLS) that is found only in nuclear proteins (reviewed in References 618 and 621 through 629). Various approaches have been used to examine import of specific proteins through nuclear pores and to define the NLSs on these proteins. The role of nuclear pores in the signal-mediated transport of nucleoplasmin (a large protein consisting of distinct head and tail domains) was demonstrated by electron microscopy using the nucleoplasmin tail (which contains the NLS) coupled to spheres of colloidal gold. Following microinjection into the cytosol of *Xenopus* oocytes, the attached nucleoplasmin tails direct entry of the gold particles into the nucleus via the nuclear pores.[630] Defining the NLSs on proteins usually involves examining the fate of altered proteins in which mutations or deletions are made in a putative localization motif; this allows a determination of the sequences necessary for nuclear import. To determine whether the signal is sufficient for nuclear import, the putative NLS is linked to a cytosolic reporter protein.

Nuclear transport can be resolved into two steps: energy-independent targeting followed by ATP-dependent translocation, which is rate-limiting (reviewed in Reference 625). These two phases of import to the nucleoplasm are mediated by at least two functionally and biochemically distinct classes of NLSs.[622,628] NLSs were first identified in the large viral protein called T-antigen, which is encoded by SV40 (the Simian virus 40), and is needed for viral DNA replication in the host cell nucleus.[631,632] Many eukaryotic nuclear proteins carry T-antigen-like NLSs; these are related to the single motif of the SV40 large T-antigen NLS, comprised of a short stretch of basic amino acids (**PKKKRKV**) or the bipartite nuclear localization motif of nucleoplasmin — two regions of basic amino acids separated by a spacer of more than four residues (**SPPKAVKRPAATKKAGQAKKKKLDKEDES**).[633] Mating type (Mat) α2-like NLSs consist of a short hydrophobic region that contains one or more basic amino acids (**KIPIK**); in contrast, the NLSs of some viral nuclear proteins are quite different (e.g., AAFEDLRVRS is the NLS of the influenza ribonucleoproteins). However, widely distinct from all these signals are those comprised of a trimethylguanosine cap that have been found in U snRNPs and at least one U snRNA-binding protein.[634]

Nuclear import is thought to involve at least two parallel nuclear localization pathways whereby targeting to the nuclear pore complex is mediated by a separate apparatus.[625] Proteins bearing T-antigen-like NLSs compete for a common receptor; the nuclear pore complex-mediated import of U1, U2, U4, and U5 snRNPs occurs by a kinetically distinct targeting pathway (see Reference 635 and references therein).

In vitro studies in which nuclear import is reconstituted indicate that isolated nuclei are not sufficient to support nuclear import; cytosolic factors including NLS binding proteins and chaperones are required. An *in vitro* nuclear transport assay,[636] in which cytosolic extracts from *Xenopus* oocytes were added to digitonin-permealized cultured BRL cells, was used to fractionate and reconstitute the import process.[637] A pivotal finding was that separate cytosolic factors act in concert to mediate both the targeting and translocation phases of nuclear import. One fraction (an NEM-sensitive fraction, termed A) is thought to contain the targeting apparatus and to mediate the association of the protein with the nuclear envelope; the second fraction (B) was derived from a whole-cell extract containing soluble components from both the cytosol and nucleus, and promotes the ATP-dependent translocation of nuclear envelope-bound proteins into nuclei (reviewed in Reference 625).

Biochemical, functional, and genetic approaches have been employed in studies to isolate nuclear import factors and elucidate their specific functions (e.g., as putative receptors for signal recognition) and import factors that stimulate translocation (reviewed in Reference 624). Import receptors are expected to recognize NLSs, stimulate nuclear translocation, and interact with the nuclear pore complex. NLS-binding proteins have been identified by various means, including NLS affinity chromatography.[638] Only partial fulfillment of these properties is satisfied by putative receptors isolated so far. Purified binding proteins from anucleate bovine erythrocytes (putative NLS targeting receptors) are able to stimulate nuclear import in permealized cells;[639] however, a further finding is that multiple NEM-sensitive cytosolic factors are required for nuclear import, one of which has an NLS binding activity. More recently, reconstitution of the first step of nuclear transport (binding to the pore complex), occurred in permealized animal cells using two purified components — a previously identified NLS receptor and a 97-kDa protein of bovine erythrocytes.[640] Phosphorylation-dependent NLS-binding proteins (NSP70s) are also likely candidates for NLS receptors, and have been identified in a number of eukaryotes, including yeast, fruit flies, human cell cultures, and corn.[641] These proteins may be highly conserved because antibodies against yeast NSP70 inhibit *in vitro* protein import into permealized *Drosophila* cells. Further studies will be needed to systematically determine which proteins having NLS-binding activity are functional in nuclear import assays; and conversely, which of the functionally defined NEM-sensitive import factors and genetically defined import factors also demonstrate NLS-binding activity. Also requiring investigation are the mechanisms by which receptors interact with the nuclear pore complex; for example, whether any pore proteins mediate this event.[624] The available evidence suggests that NLS-binding proteins are able to recognize diverse NLSs, and that only a few types of import receptors are required for protein import. Also being characterized are the integral proteins of the nuclear pore complex that may have roles in the anchoring of the complex in the nuclear pore and regulation of nucleocytopathic traffic through the NPC.[642,643]

Chaperone proteins of the stress-70 families (Hsp70 and Hsc70) function in nuclear import,[644] although it is not clear yet whether their role is a direct or indirect one. For example, it has not been shown whether they interact directly with proteins destined for the nucleus or with a component of the translocation apparatus.[625] Stress-70 proteins function during transport into the ER lumen (see earlier) to help maintain nascent precursors in an extended conformation required for translocation competence; a similar facilitory process occurs during translocation of proteins into other organelles (e.g., chloroplasts and mitochondria). However, unlike proteins translocated into these organelles, proteins are generally not imported into nuclei as extended polypeptide chains.[622,625,628] Multisubunit proteins and RNPs with diameters in excess of 20 nm (the approximate dimensions of a 500-kDa spherical protein) are imported; karyophilic gold particles of 26 nm can also be accommodated by the translocation apparatus. What, then, is the specific role of these chaperone proteins in nuclear import? One suggestion is that stress-70 proteins bind to the surface of folded proteins destined for import and affect the exposure or conformation of the NLS;[625] indeed, the context of the NLS has been demonstrated to be important in the efficiency of nuclear import (reviewed in Reference 618). Another suggestion is that they may associate with a component of the cytosolic or nuclear pore complex-associated apparatus. A role in the disassembly of a targeting complex with the nuclear pore complex represents another possibility, somewhat similar to the role of the uncoating ATPase of clathrin-coated endocytic vesicles.[368] Finally, it cannot be ruled out that the stress-70 proteins may serve as the ATP-hydrolyzing motor that catalyses vectorial translocation through the nuclear pore complex-associated cytoplasmic filaments.[622]

As mentioned earlier, in all eukaryotic cells, there must be developmental and environmental controls over the nuclear import of certain proteins. Thus, although NLSs often function constitutively, their activity can also be regulated by phosphorylation of amino acids that are a component of, or flank, the NLS, or by distant regions of the polypeptide chain that can either mask the signal or anchor the protein in the cytoplasm (reviewed in Reference 645; see references therein). A striking example of regulated nuclear import and its role in the control of gene expression is the dorsal protein of *Drosophila*. This protein is the morphogen that determines the dorsoventral polarity of the embryo. It is found in the cytoplasm during early development; however, during cleavage it becomes localized to the nucleus exclusively in the ventral portion of the embryo, where it activates the transcription of the ventralizing genes, *twist* and *snail*. Aberrant development occurs when this regulation of nuclear transport fails. There are also examples of proteins with both constitutive and regulated NLSs; one such protein is the nuclear oncoprotein encoded by the adenovirus type 5 *Ela* gene. The constitutive NLS is of the SV-40 type and is located in the C-terminus, whereas the regulated NLS has a nonconventional motif and resides within amino acids 140–185. The latter can direct nuclear import in injected *Xenopus* oocytes, but not in transfected cells, providing evidence for its regulated nature. Nuclear import via the regulated NLS is ATP-dependent and competes with the C-terminus NLS. In DNA-injected fertilized *Xenopus* eggs, the NLS directs nuclear import up until the early neurula stage in all embryonic tissues; subsequently, the use of the NLS is turned off in specific tissues at specific times. Thus, there appears to be a hierarchy among the embryonic germ layers as to when the second signal becomes nonfunctional.[645]

3. Nuclear Import and Export of Proteins that Undergo Shuttling

As mentioned earlier, some proteins continuously shuttle between the nucleus and the cytoplasm. Some of the proteins may be transported via substrates to which they are bound and disso-

ciate only after crossing the nuclear envelope. For example, certain nuclear mRNP proteins associated with mRNA transport, which do not necessarily function directly in transport, are shed only after the mRNP is exported to the cytoplasm. These mRNPs are subsequently recycled back to the nucleus.[646] Shuttling may also be a common property of signal receptors and chaperones in nuclear transport. Oocyte stress-70 proteins, for example, shuttle between the cytoplasm and the nucleus;[647] likewise, binding proteins that recognize NLSs on nucleolar proteins and unique components participating in the export of ribosomal subunits to the cytoplasm are likely in dynamic equilibrium across the nuclear envelope, undergoing frequent shuttling. The nucleolar transport factor, Nopp140 from rat liver, binds NLS sequences and is localized predominantly to nucleoli but can be found in the nucleoplasm and transiently in the cytoplasm, even in the absence of protein synthesis.[648] Shuttling is suggested to occur along linear tracks that extend from sheet-like structures in the nucleolar interior out through the nuclear pore complexes into the cytoplasm.[648] In addition to mediating carrier-type functions, a further role of the shuttling process may be to mediate feedback control on the synthesis of nuclear proteins at the levels of translational control or mRNA degradation.[621]

It is now clearly established that shuttling does not require specific export sequences and that it can be decreased by sequences that promote binding in the nucleus (reviewed in Reference 621). The relative contributions of selective retention and selective entry to protein accumulation in the nucleus have also been examined. The view most supported by the available evidence is that, although import into the nucleus is a selective process, accumulation can be reinforced by selective binding once a protein has been transported into the nucleus.[649] Without this selective binding, some nuclear proteins will escape and shuttle repeatedly between the nucleus and the cytoplasm. Clearly, there are proteins of the nucleus that do not exhibit shuttling activity, but rather, are stably retained within the nucleus. One such protein is lamin B2, which comprises part of the nuclear lamina; removal of sequences required for its incorporation into the lamina converts it from a nonshuttling to a shuttling protein.[621] The question of whether export of shuttling proteins is a passive or active process has also been addressed, but has yielded conflicting results. However, it is clear that exported mRNAs and ribosomal subunits leave the nucleus much faster than the smaller shuttling proteins, which further supports the view that RNP export is a facilitated, energy-dependent process.

4. Nuclear Transport In Plants

Recent studies have yielded some information on the requirements for nuclear import in plant cells.[618,650-667] As in studies of other eukaryotic organisms, the two criteria used to define the NLSs of plant nuclear proteins are (1) sequences necessary for correct localization of the protein within the nucleus; deletion or mutation of certain key sequences within the NLS results in a loss of nuclear transport or inefficient transport leading to localization in both the cytoplasm and the nucleus; and (2) sequences sufficient to redirect a cytoplasmic reporter protein to the nucleus.[618] Transient expression systems using tobacco protoplasts or onion epidermal layers have been particularly useful.

Efforts have been made to determine whether the localization signals of other eukaryotic nuclear proteins are recognized in plant cells.[654,657] As mentioned earlier, the SV40 large T-antigen contains a short stretch of basic amino acids (**PKKKRKV**) that serves as a signal for entry of the viral protein into the animal cell nucleus and is also found in a number of other eukaryotic nuclear proteins. This nuclear localization motif is also recognized in plant cells. Transient expression of a T7 RNA polymerase gene in tobacco protoplasts results in nuclear localization of the corresponding protein, provided the gene construct is modified to contain sequences encoding the NLS of the SV40 large T-antigen.[654] Likewise, a chimeric protein, comprised of the 7 amino acid T-antigen NLS fused to the cytosolic GUS protein, localizes to the nucleus in transformed tobacco cells.[657] A mutant form of the NLS, in which an essential K residue is mutated to T, abolishes nuclear transport of the GUS protein. Thus, at least some aspects of nuclear transport are common between plant and animal cells.

a. Nuclear Localization of Gene Regulatory Proteins

The nuclear import mechanisms of two gene regulatory proteins from maize have been analyzed.[618,658-660,667] Opaque-2 is a *trans*-acting factor that regulates the expression of the 22-kDa zein genes of maize;[668] it belongs to the basic domain, leucine-zipper (bZIP) class of proteins. It localizes to the nucleus in maize endosperm tissue and, when expressed in transgenic tobacco, the fidelity of nuclear transport is preserved.[658] Further, a chimeric protein comprised of Opaque-2 linked to the normally cytosolic GUS, is correctly localized to the nucleus in both transgenic tobacco and transiently transformed onion cells.[659] Two independent domains of the Opaque-2 protein are sufficient to redirect the GUS reporter protein to the nucleus: (1) NLS A, located between the two transcriptional-activating domains, that has a SV40-type motif and is less efficient in directing GUS to the nucleus; and (2) NLS B, located in the highly conserved DNA-binding domain, having a bipartite structure and characterized by being more efficient in directing nuclear transport of GUS. To date, studies of two other bZIP proteins from plants (TGA-1a and TGA-1b) and three bZIP proteins from animals (Fos, Jun, and Eb1) have localized the NLSs within the basic domain associated with DNA binding.[657,666,669,670] Both NLS A and NLS B are necessary for nuclear targeting of Opaque-2.[660] Further analysis of the NLS B region of Opaque-2 to identify the critical amino acid residues reveals that both the bipartite structure and the net basic amino acid content are important for nuclear targeting. A mutation that contains altered amino acids on both parts of the bipartite NLS severely reduces nuclear targeting; this led to the definition of two classes of bipartite NLSs, distinguished by the presence or absence of acidic amino acids in the spacer region between the two basic motifs. Analysis of a mutant form, in which a conservative mutation is made within NLS B, demonstrates that the nuclear targeting function of this domain is independent of DNA-binding; while completely abolishing DNA binding, the mutation leaves nuclear targeting unaffected. The bifunctionality of this domain may be conserved in all members of the leucine zipper class; to attain DNA-binding specificity, basic amino acids may require a specific arrangement in the proper configuration for NLS function.[660] Biochemical studies of transport into isolated plant nuclei using the Opaque-2 bipartite NLS (and various mutant forms) may aid in identifying putative receptor proteins in plant cells.[661]

Another transcription-activating protein from maize (R protein) contains a helix-loop-helix motif similar to those found within a number of animal transcriptional activators (e.g., myo D1 and myc).[671] Fusion proteins in which the R protein is linked to GUS are successfully targeted to the nucleus in onion epidermal cells, regardless of whether the R protein portion of the chimeric protein is at the N-terminus or C-terminus (i.e., R-GUS or GUS-R, respectively).[667] Further analysis of chimeric constructs containing different regions of the R gene fused to the GUS gene coding region led to the identification of three specific NLSs capable of redirecting the GUS protein to the nucleus. The first of these is a 10 amino acid N-terminal NLS-A, comprised of several arginine residues; a similar localization signal is present in only a few viral proteins. The medial NLS-M (also comprised of 10 amino acids) contains an SV-40 motif, and the carboxy-terminal NLS-C is a MAT α-2 type. NLS M and C are independently sufficient for nuclear transport when fused to the amino-terminus of GUS; these two nonhomologous signals may be involved in different steps of nuclear transport or may interact with different import components of similar function.[618] NLS A fused to GUS leads to partitioning of the chimeric protein between the nucleus and cytoplasm. The position of the NLS in the transported protein is important; partitioning between the nucleus and cytoplasm also occurs when all three NLSs are independently fused to the C-terminal portion of GUS.[667] Deletion analysis of the three specific NLSs reveals that multiple signals are necessary for nuclear targeting of the R protein. Only the combined action of NLS A and M, or NLS C and M, are able to direct nuclear localiza-

tion. GUS fusions comprised of all other combinations become localized in both the nucleus and the cytoplasm.

b. Nuclear Localization of Plant Virus Proteins

Plant viruses often encode a number of different proteins that accumulate in different subcellular compartments after infection. Members of the potyvirus group form characteristic inclusions after infection, including nuclear inclusions composed of two proteins involved in replication of potyviral RNA, NIa and NIb.[655] The role of nuclear transport of the two proteins is somewhat puzzling because RNA replication apparently occurs within the cytoplasm. Fusion of either NIa or NIb to GUS is sufficient to direct GUS reporter activity to the nucleus in transfected protoplasts and stably transformed tobacco plants. Deletion analysis of the NIa gene identified a bipartite NLS within the protein consisting of two short regions (comprised of 11 and 30 amino acids, separated by 32 residues) located within the amino-terminal region of the protein.[650] Deletion and mutational analysis of NIb yields a somewhat different scenario.[665] Amino acid changes affecting two areas, between residues 3–5 and 303–306, abolished nuclear transport. However, the assignment of NLS function to these regions is complicated by the finding that substitutions at four additional sites throughout the NIb sequence also render fusion proteins primarily cytoplasmic. Further, each of six deletions in NIb debilitates nuclear localization, regardless of whether the basic clusters are deleted. Insertion of Pro-Pro dipeptides, predicted to lead to abnormal folding of NIb, reduces nuclear import when placed at three out of four positions. Thus, nuclear localization of this protein may require a stringent tertiary structure in addition to one or more NLSs.[665]

c. Nuclear Localization of Nucleic Acids during Agrobacterium*-Mediated Plant Transformation*

Agrobacterium tumefaciens is a soil pathogen capable of infecting a number of plant species (primarily dicots) and inducing crown gall disease. Tumorous growths (crown galls, characterized by continuous cell division) arise on these plants at wound sites as a consequence of the production of growth hormones (auxin and cytokinin) in infected and transformed plant cells. A large plasmid within the bacterium (the Ti plasmid) effects the transfer of tumor-inducing genes (genes encoding enzymes required for the biosynthesis of the hormones) as a single-stranded DNA molecule to the plant nuclear genome (reviewed in Reference 672). The T-DNA of *Agrobacterium* is transferred to the plant cell and eventually to the plant nucleus as a complex of three components: a single-stranded DNA molecule, the T-strand, and two different virulence proteins — vir D and vir E. The vir D2 protein attaches covalently to the 5′ end of the T-strand; over 600 copies of the vir E2 protein bind along the length of the T-strand, making the entire T-complex approximately 60 times longer than the diameter of the nuclear pore.[651] The vir D2 protein that is tightly attached to the T-DNA is thought to pilot the T-strand to the plant nucleus. A bipartite NLS at the carboxy-terminus of vir D2 is sufficient for nuclear import of GUS; it also appears to be sufficient for efficient T-DNA transfer to the plant cell nucleus.[652,653,662–664] The vir E2 protein may also play an important role in nuclear transport of the T-strand.[651] When vir E2 is fused to GUS, the chimeric protein localizes to the nucleus in tobacco cells; a role *in planta* is suggested by the finding that tumorgenicity of an avirulent vir E2 mutant is restored when inoculated on transgenic plants expressing the vir E2 protein. Nuclear localization of vir E2 is mediated by two bipartite NLSs (NSE1 and NSE2), and efficient nuclear localization of GUS is achieved only when both signals are present. An interesting suggestion is that vir E2 acts as a molecular chaperone serving to coat, unfold, and target the T-strand to the nucleus. Further studies to elucidate the cooperation between the two virulence proteins in effecting nuclear transport of the T-DNA are awaited with interest.

VIII. PROTEIN TARGETING INTO PEROXISOMES AND GLYOXYSOMES

Peroxisomes (microbodies) are thought to be present in all eukaryotic cells; they share a num-

ber of common characteristics, as well as some unique ones, depending on the organism and developmental stage. All of these organelles, regardless of their origin, are bounded by a single membrane, do not possess an organelle genome, and contain catalase for the breakdown of hydrogen peroxide (reviewed in References 673 and 674). Although they do not contain any internal membrane structure, the matrix of the organelle occasionally contains crystalline or fibrillar inclusions that contain enzymes. Their constituent proteins are encoded by nuclear genes, are synthesized on free polyribosomes, and are imported from the cytosol. Higher plants contain several classes of peroxisomes that carry out different metabolic roles; these are found during different stages of the plant lifecycle and may be species-, organ-, or cell-specific.[675] At least three classes of peroxisomes (microbodies) have been defined: (1) glyoxysomes, present in postgerminative seedlings and senescent organs, that function in the mobilization of seed storage lipids by housing the enzymes of the glyoxylate cycle;[676–678] (2) leaf-type peroxisomes, present in photosynthetically active tissue, that contain enzymes essential for the light-dependent reactions of photorespiration, including glycolate oxidase and hydroxypyruvate reductase;[677,679] and (3) specialized peroxisomes in root nodules of certain legumes, which contain urate oxidase involved in the production of ureides, the primary nitrogenous products exported from nodules. In addition, plant organs (e.g., roots) also contain unspecialized peroxisomes without defined metabolic roles.[677,680] Plant peroxisomes are functionally adaptable organelles; they can change their specialized metabolic roles (dictated by the unique set of enzymes that they accumulate) in response to the specific requirements of the cell that are, in turn, dependent on the specific developmental stage. For example, during seedling development, these organelles undergo an interconversion in function during the transition from heterotrophic to autotrophic growth.[681–685] During greening of cotyledons, glyoxysomes are converted to leaf peroxisomes, which function in photorespiration. During senescence of leaves and cotyledons, a reverse transition occurs and glyoxylate cycle enzymes are once again found in peroxisomes; enzymes characteristic of both pathways coexist within the same organelle at the stage of transition from peroxisome to glyoxysome.[681,683,684]

Insight into the mechanisms for targeting proteins to peroxisomes in plants has been derived by studies of protein import *in vivo* (e.g., examining the subcellular localization of peroxisomal proteins in transgenic hosts); *in vitro* import systems using isolated organelles have also been developed. A carboxy-terminal tripeptide conforming to the consensus sequence S/A/C-K/R/H-L (the so-called SKL motif) has been identified as a conserved peroxisomal targeting sequence.[686] The initial characterization of this signal was based on gene transfer experiments with the firefly luciferase gene,[687] which showed that the carboxy-terminal three amino acids (SKL) of the luciferase enzyme are both necessary and sufficient for routing of the protein into peroxisomes. Correct routing of firefly luciferase into the peroxisomes of diverse organisms reveals a conservation of the signal recognition process and import mechanism;[688] furthermore, the tripeptide motif is present at the carboxy-terminus of many peroxisomal enzymes from animals, plants, and yeast (reviewed in Reference 689). Despite the remarkable conservation of this C-terminal targeting signal, there is substantial evidence in all eukaryotic organisms that multiple signals are involved in the targeting of peroxisomal matrix proteins. Further, if a tripeptide motif is involved, it need not be located at the extreme carboxy-terminus of the protein. An internal SHL sequence occurs within the 27 amino acid C-terminal topogenic peptide of human catalase; likewise, a signal in rat thiolase is able to specify peroxisomal import, even though located internally (reviewed in References 689 and 690). The peroxisomal targeting signal of rat liver acyl-CoA oxidase resides in the carboxy-terminus of the protein; however, the same enzyme from *Candida tropicalis* contains two internally located regions consisting of about 100 amino acids that function in peroxisomal import. An amino-terminal-targeting signal has been identified in rat liver peroxisomal 3-ketoacyl-CoA thiolase.[690]

A survey of the carboxy-terminal sequences of plant peroxisomal proteins shows that many, but not all, contain a terminal tripeptide that is

similar to the luciferase consensus sequence (reviewed in Reference 673; see references therein) (Table 11). However, on some plant proteins, potential targeting determinants are also found upstream of the carboxy-terminus. For example, catalase and hydroxypyruvate reductase from cucumber lack the terminal tripeptide, but contain a similar tripeptide several amino acids upstream. Uricase and glycolate oxidase may contain two of these putative targeting sequences, separated by a single amino acid residue. The glyoxysomal enzymes isocitrate lyase and malate synthase contain a carboxy-terminal tripeptide similar to luciferase and other peroxisomal proteins. However, experiments to determine the function of the carboxy-terminal tripeptide on castor bean isocitrate lyase reveal that it is not essential for import into glyoxysomes in an *in vitro* system.[691]

The import of *in vitro*-synthesized isocitrate lyase into glyoxysomes isolated from sunflower cotyledons is temperature and ATP dependent. Progressive carboxy-terminal truncations of the isocitrate lyase gene were transcribed and translated to yield polypeptides with the same amino-terminus, but lacking in varying amounts of the carboxy-terminus. All of the truncated polypeptides were imported with the same characteristics as the full-length protein, suggesting that the targeting information resides within the first 168 amino acids. Thus, the carboxy-terminus containing the luciferase-like tripeptide is dispensable for targeting and import.[691] The putative C-terminal targeting signal on glycolate oxidase has also been tested for functionality in transgenic tobacco;[692] the last six C-terminal amino acids of the peroxisomal protein are sufficient to target cytosolic GUS to tobacco leaf peroxisomes. The carboxy-terminus of watermelon malate dehydrogenase does not contain an obvious targeting tripeptide, but this protein has an amino-terminal

extension that may play a role in transport.[693] This extension is comprised of 37 amino acids, has a net positive charge, lacks a long stretch of hydrophobic residues, and contains a cluster of serine residues; an AHL tripeptide within the extension may represent the necessary topogenic information. Notably, the N-terminal extension is cleaved off when associated with, or imported into, glyoxysomes. It has been suggested that at least two distinct import pathways exist for peroxisomal proteins that contain uncleavable C-terminal signals, versus those that contain peroxisomal import signals comprised of an N-terminal, cleavable presequence.[694] The precursor watermelon malate dehydrogenase is correctly targeted to and imported into peroxisomes of the methylotrophic yeast *Hansenula polymorpha*, indicating that the targeting signal of the plant protein is correctly recognized in this heterologous host. However, processing of the N-terminal sequence does not occur, suggesting that a specific peroxisomal peptidase is either absent or does not recognize processing signals within the heterologous protein.[694]

In addition to the diversity of signals that mediate the import of matrix proteins, there is evidence that peroxisomal membrane proteins use alternative mechanisms; these proteins do not contain motifs similar to matrix-directed proteins such as luciferase. The existence of multiple peroxisomal signals has been particularly important in elucidating the protein targeting defect in humans that exhibit Zellweger syndrome. Membrane ghosts prepared from peroxisomes of certain Zellweger patients import the thiolase precursor, but fail to import other proteins such as acyl-CoA oxidase and catalase. Thus, the cells from these patients are competent to import proteins containing only one type of peroxisomal targeting signal and are incapable of recognizing signals of the SKL-type.[695] This likely indicates that the proteins containing thiolase- or SKL-type targeting signals are recognized by different receptors.[686] An intriguing question to be addressed is whether these receptors interact with the same or independent translocation machinery to facilitate import.

To examine the participation of integral membrane proteins in the import of proteins into plant glyoxysomes, a radioactively labeled peptide having a sequence corresponding to the last 12 amino acids of rat acyl-CoA oxidase (D-Tyr-HKHLKPLQSKL) was used to detect a receptor capable of recognizing the SKL motif.[696] Binding of the radiolabeled peptide to alkali-stripped glyoxysomal membranes is saturable, and 80% of the binding can be replaced by unlabeled peptide or glyoxysomal matrix proteins. Protease treatment of the alkali-stripped glyoxysomal membranes lowers the number of high affinity sites and destroys all low affinity sites. Characterization of specific receptor proteins involved in peroxisomal import in plants is awaited with interest.

Further elucidation of the requirements for peroxisomal targeting and import have come from studies on animal proteins. In firefly luciferase, recognition of the tripeptide signal is context dependent[687] (reviewed in Reference 686). Linker insertions within the amino-terminal half of the enzyme as well as large fusions between cytosolic reporter proteins and luciferase produce chimeric polypeptides that fail to be transported into peroxisomes, even though the signal is present at the carboxy-terminus. Thus, the signal likely must be accessible in the folded protein. Because many peroxisomal proteins are synthesized at the mature size, few studies have addressed the involvement of molecular chaperones in peroxisomal targeting. However, recent findings support the role of chaperones in maintaining peroxisomal proteins in a conformation-competent conformation.[697] Import of catalase into peroxisomes is retarded when assayed in the presence of aminotriasol, a specific inhibitor of catalase activity. The drug is likely to hinder the unfolding of catalase preventing it from assuming a translocation-competent state; alternatively, it may mask the targeting signal.[698] Further, the translocation of peroxisomal proteins (e.g., acyl-CoA oxidase, isocitrate lyase) requires ATP hydrolysis,[691,699] which mediates chaperone-assisted translocation of proteins into other organelles (e.g., those undergoing translocation across the membranes of the ER, chloroplast, and mitochondrion). Interestingly, a 72-kDa protein that binds to clofibrate (an inducer of peroxisomal proliferation) is a member of the stress-70 protein family.[700]

A pertinent question addressed in plants is whether the metabolic role of a peroxisome is determined by the capacity of the organelle to recognize targeting signals of only a subset of proteins.[674,675] This was investigated in relation to

the developmental transition of peroxisomal function by analyzing the targeting of glyoxysomal proteins (characteristically synthesized during postgerminative growth of seedlings or during senescence) to leaf-type and root peroxisomes. When the glyoxysome-specific enzymes isocitrate lyase and malate synthase are synthesized in transgenic *Arabidopsis*, they are imported into leaf-type and root peroxisomes; furthermore, the same targeting determinant is recognized by different classes of the organelle. The ability of glyoxysomal proteins to be transported into several classes of peroxisomes using a common targeting determinant suggests that protein import does not play a regulatory role in determining peroxisomal metabolic function. Rather, the specific metabolic role of this organelle may be dictated primarily by controls over the synthesis/stability of its constituent proteins. These "upstream" controls are in turn specified by the differentiated state of the cells in which the organelles are found.[674]

IX. PROTEIN TARGETING INTO AND WITHIN CHLOROPLASTS

The chloroplast is a complex organelle that carries out a wide range of metabolic processes; in addition to housing the entire photosynthetic machinery, it is responsible for several vital biosyntheses (e.g., of fatty acids, phospholipids, and amino acids), the interconversion of carbohydrate intermediates, and the final steps in the assimilation of inorganic nitrogen and sulfate. It is a semiautonomous organelle, equipped with the machinery necessary for the transcription and translation of the limited number of proteins that are encoded by its own genome. Despite this synthetic capacity, the great majority of proteins required for chloroplast function are encoded by the nuclear genome; following their synthesis on free polyribosomes of the cytosol, they are imported into the chloroplast, where further intraorganellar sorting may take place. The complexity of the organelle at the metabolic level is mirrored by a corresponding complexity at the structural level. It consists of three distinct membrane systems (the outer and inner envelope membranes and the thylakoid membrane), which enclose three distinct soluble subcompartments (viz., the interenvelope membrane space, the stroma, and the thylakoid lumen). Thus, all six components comprise targets for protein transport (Figure 32).

Protein transport into the stroma and thylakoids has been analyzed in some detail (reviewed in References 701 through 706) and is summarized in the next sections; reference is also made to Figure 33. At present, little information is available on the mechanisms of protein targeting to the outer and inner envelope membranes or to the interenvelope membrane space.

A. Protein Targeting to the Stroma

Biogenesis and subsequent translocation of proteins across the chloroplast envelope membranes into the stromal compartment have been investigated in detail. The protein studied most extensively in this respect is the small subunit of ribulose bisphosphate carboxylase-oxygenase (SSU-Rubisco), a nuclear encoded protein. Following synthesis in the cytosol and subsequent translocation into the stroma, the SSU associates with its counterpart, the large subunit (LSU) (which is synthesized within the chloroplast) to form a large oligomeric complex comprised of eight subunits of each type.[707] The general principles derived from studies on the SSU-Rubisco appear to be valid for the transport of similarly directed proteins (e.g., ferredoxin).[701] In large part, analysis has been by *in vitro* import systems,[708] in which the transport of radiolabeled proteins (often constructed by recombinant genetic techniques and synthesized by *in vitro* transcription and translation) into purified intact chloroplasts is assessed. Verification of import can involve treatment with external proteases; membranes protect imported proteins from degradation, whereas external proteins remain susceptible. Isolated chloroplasts of pea stored in liquid nitrogen in the presence of dimethyl sulfoxide (65 to 70%) remain intact upon thawing and are fully functional in the import of precursor proteins; preserved thylakoids also exhibit near optimal activity for protein integration.[708]

Proteins that must cross the outer and inner envelope membranes (i.e., stromal proteins and other proteins that undergo further intraorganellar

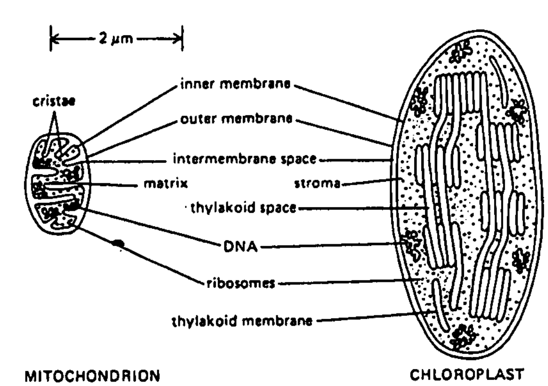

FIGURE 32. Schematic representation of a mitochondrion and a chloroplast. The chloroplast is generally much larger and contains a thylakoid membrane and thylakoid space. The mitochondrial inner membrane is folded into cristae. (From Alberts, B., Bray, D., Lewis, J., Raff, M., Roberts, K., and Watson, J., *Molecular Biology of the Cell*, 2nd ed., Garland Publishing, New York, 1989. With permission from Garland Publishing.)

targeting after reaching the stroma) are synthesized on cytosolic polyribosomes as precursors with a transient N-terminal sequence, the transit peptide. This transit peptide mediates both the initial binding of the precursor to the outer membrane of the chloroplast envelope as well as its posttranslational import. Coincident with translocation of the precursor, or shortly thereafter, a specific stromal peptidase effects transit peptide removal, yielding the mature protein. The proteolytic enzyme is chelator sensitive and is highly specific for imported precursors.[709] The precursor of SSU-Rubisco is processed to the mature size in two steps (involving the same enzyme, but different amino acid residues) and proceeds via an 18-kDa intermediate.[710,711]

The transit peptides of chloroplast proteins generally behave in an organelle-specific[712] and autonomous fashion; when attached to a heterologous (nonchloroplastic) passenger protein, (via gene fusion experiments, followed by *in vitro* transcription/translation), they are capable of effecting unidirectional import of the passenger protein into the chloroplast. Successful import into the stroma was first demonstrated with the transit peptide of SSU-Rubisco linked to bacterial reporter proteins (CAT and neomycin phosphotransferase II),[713,714] and subsequently has been shown with a number of different passenger proteins,[715-717] as well as with chimeric proteins having transit peptides from other chloroplast proteins.[701,712,718-720] Not all transit peptides may be equally efficient or competent in effecting translocation of a given passenger protein across the chloroplast membrane; likewise, different passenger proteins linked to the same transit peptide exhibit differences in the extent and efficiency of import.[702] Import of chimeric proteins can (in some cases) be increased when part of the mature chloroplast protein is added (in addition to the transit peptide), but this is not always a consistent result, and may, in part, be due to structural reasons (e.g., maintaining a particular secondary or tertiary configuration of the transit peptide that is conducive to import; see later discussion).[715,716,721,722] More systematic and quantitative studies are needed to evaluate these results.

Attempts to define the functional domains of transit peptides (e.g., those sequences involved directly in receptor binding or translocation) have

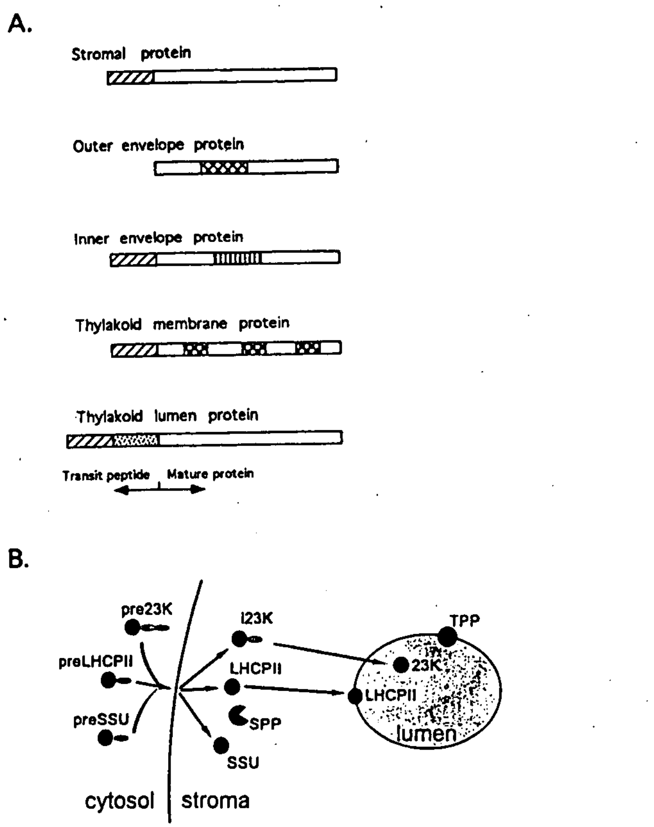

FIGURE 33. (A) Targeting information in chloroplast precursor proteins. In each protein, the mature portion is represented by the region indicated at the bottom of the figure. The right-leaning hatched bar represents an envelope transfer sequence; the spotted bar represents a thylakoid transfer sequence. Other topogenic sequences (cross-hatched bar, the outer envelope targeting domain; vertical-striped bar, the inner envelope targeting domain; checkerboard bar, the thylakoid membrane targeting signal patches) reside within the mature portion of the proteins and are poorly characterized; their relative positions are arbitrary. (From Theg, S. M. and Scott, S. V., *Trends Cell Biol.*, 3, 186, 1993. With permission from Elsevier Publishing, Cambridge.) (B) Basic pathways for the import of proteins into the chloroplast stroma, thylakoid membrane, and thylakoid lumen. The diagram depicts the basic import pathways for a stromal protein, Rubisco small subunit (SSU), a thylakoid membrane protein, LHCPII, and a thylakoid lumen protein, 23K. SSU and LHCPII are synthesized with stroma-targeting presequences (black ovals), which mediate binding to receptors on the chloroplast surface and transport across the envelope membranes. 23K is synthesized with a bipartite presequence containing a similar stroma-targeting signal followed by a thylakoid-transfer signal (hatched oval). The stroma-targeting signals of all three precursors are removed by the stromal processing peptidase (SPP). LHCPII inserts into the thylakoid membrane by means of signals in the mature protein, whereas the cleavable thylakoid transfer signal of 23K mediates translocation across the thylakoid membrane. Insertion of LHCPII requires ATP and a stromal protein factor; the requirements for thylakoidal protein translocation are shown in greater detail in Figure 34. (From Robinson, C. and Klösgen, R., *Plant Mol. Biol.*, 26, 15, 1994. With permission from Kluwer Academic Publishers.)

taken the form of two general approaches (reviewed in Reference 702). One approach has been the comparative analysis of the primary (and to a lesser extent, secondary) structures of transit peptides.[702,723] The other general approach has been to address structure-function relationships by generating and analyzing deletions (or specific changes to amino acid residues) in various regions of the transit peptide (e.g., those of ferredoxin and SSU-Rubisco).[721,724-728] With respect to the first approach, the amino acid sequences of the SSU-Rubisco transit peptides have now been determined from 48 genes representing 22 plant species.[702] From the statistical analyses of these and other transit peptides (e.g., those of other stromal and thylakoid membrane/lumen precursors), the general picture that emerges is that sequence similarities generally exist among transit peptides of the same precursor derived from different plant species. Few similarities are found among different precursors, even when the precursors are derived from the same plant species.[702] Despite the general lack of primary sequence similarities among transit peptides, some common features have emerged. They are rich in hydroxylated amino acids, serine and threonine, and also have a number of small hydrophobic amino acids such as valine and alanine. A general lack of acidic amino acids is evident; overall, they have a net positive charge.[702,723]

Small deletions in the transit peptide of SSU-Rubisco generally do not abolish import into chloroplasts.[724,725] Mutagenesis experiments (to effect changes in specific amino acid residues in various regions of the transit peptide) indicate that N-terminal and C-terminal sequences may be essential for binding and/or uptake.[701,725-727] However, the general concept emerging is that the essential features of transit peptides are not found in their amino acid sequence, but rather in some higher-order structure. Thus, specific conserved secondary or tertiary structural features in the transit peptide may be more important in signal recognition/decoding by receptors or other components of the import/translocation machinery.[701,702] The presequences of several mitochondrial proteins have the capacity to form amphiphilic structures (see later discussion), and amphiphilicity may be one essential feature of their function.[729,730] However, there are numerous differences between the topogenic signals of mitochondrial and chloroplastic proteins, such as absolute amino acid composition, length, and predicted secondary structure.[723] Furthermore, the presence of amphipathic β-sheet structures (predicted by hydrophobic moment analyses; see later discussion) has not been confirmed for chloroplastic peptides.[704,723] An alternative view is that chloroplast transit peptides are designed to be devoid of any regular secondary or tertiary structure.[731] If they are indeed 'perfect random coils,' a series of interactions with cytosolic and chloroplastic chaperones may be all that is required for chloroplast targeting and import.[731]

B. Protein Targeting Toward the Thylakoid Membrane System

The thylakoid membrane system encloses the thylakoid lumen and is itself completely surrounded by stroma. Thus, proteins destined for either subcompartment must undergo further intraorganellar targeting following their import into the stroma. Proteins of the thylakoid membrane or lumen utilize a targeting mechanism that consists of two independent steps; information is encoded for the sequential translocation across the outer and inner envelope membranes (envelope targeting signal) and for the integration into (or translocation across) the thylakoid membrane (Figure 33).[720,732-734] The most abundant thylakoid membrane protein imported from the cytosol is the light-harvesting chlorophyll binding protein (LHCP) of photosystem II. The transit peptide of this protein directs import of precursor into the stroma while the signal for subsequent insertion into the thylakoid membrane is encoded in the mature protein.[718,734,735] Stable integration into the thylakoid membrane may involve complex interactions between membrane-spanning domains and other domains in the mature protein, which have importance in protein refolding.[734,736] A soluble proteinaceous stromal factor is also required;[737] its primary function may be to maintain the solubility and integration competence of LHCP.[738] Proteolytic cleavage of LHCP to its mature size occurs only after membrane insertion is completed.[739] However, despite the lack of a thylakoid network in albinoid petunia protoplasts,

transient expression of the LHCP gene within this system yields a protein that is promptly processed into its mature-cleaved form.[740] The site of integration appears to be the exposed stromal (unstacked) thylakoid regions; from this site, LHCP diffuses to its final destination in the stacked granal membranes.[741] There is an energy requirement for integration of LHCP that can be met by ATP but is considerably more efficient when there is also a proton motive force (PMF) across the thylakoid membrane (see later discussion).[742]

The targeting and assembly of thylakoid membrane proteins are highly complex processes that appear to be specific and characteristic for each polypeptide species. For example, the apoprotein of the chlorophyll a/b antenna complex CP24 of photosystem II is a remote relative of the light-harvesting complex (LHC) apoproteins. However, the CP24 displays unique structural differences to LHC apoproteins that have a potential impact on the routing and targeting processes during biogenesis.[743] In particular, CP24 lacks a pronounced second hydrophobic segment present in the mature polypeptide chain of LHCPs, and carries a transit peptide that is reminiscent of thylakoid-targeting transit peptides (see subsequent discussion). Experiments using both radiolabeled authentic precursor and chimeric proteins demonstrate that the transit peptide of the CP24 apoprotein is required only for import of the protein into the organelle. All subsequent steps, such as integration of the protein into the thylakoid membrane, binding of chlorophyll, assembly into the CP24 complex, and migration to the grana lamellae still take place if the authentic transit peptide is replaced by a targeting signal of a nuclear-encoded stromal protein.[743]

Nuclear-encoded thylakoid lumen proteins must transit all three chloroplast membranes (viz., the outer and inner membranes of the envelope and the thylakoid membrane) and hence, have a uniquely complex import pathway (reviewed in References 703 and 706). Domain swapping and fusion experiments with lumen proteins such as plastocyanin (a small hydrophilic electron carrier) and the 33- and 23-kDa proteins of the photosynthetic oxygen-evolving complex have provided strong evidence for two separate steps in the transport process.[703,719,720,732,733] Moreover, these two distinct targeting events (viz., transport across the chloroplast envelope and subsequent translocation across the thylakoid membrane) are directed by a composite transit peptide that has two functionally independent domains (Figure 33). The bipartite structure is comprised of a N-terminal domain, which is structurally and functionally analogous to the transit peptides of stromal proteins, followed by a more hydrophobic domain (responsible for targeting across the thylakoid membrane).[701,702] Interestingly, the latter strongly resembles the signal sequences of secretory proteins in bacterial and eukaryotic cells.[744] It is noteworthy that precursor maturation also occurs in two sequential steps that require different proteases; one is located in the stroma and yields an intermediate protein form; the other is present as an integral membrane protein and generates the mature protein.[732,733,745–749] The thylakoid processing peptidase is capable of cleaving signal peptides of secretory proteins of both eukaryotic and bacterial origin (see Reference 701 and references therein). The site utilized by the stromal processing enzyme occurs within a central region of the transit peptide; the enzyme recognizes a motif that is common to the transit peptides of both stromal and thylakoid luminal proteins and is surrounded by a common secondary structure (predicted β-turn/β-sheet/α-helix structure). This structural similarity may be indicative of a selective pressure to maintain common sites on these precursors for recognition by the stromal processing peptidase.[750]

In vitro assays for the import of proteins by isolated thylakoids have been refined and optimized facilitating investigation of the specific requirements for targeting; in some cases import efficiencies approaching 100% have been achieved (e.g., for the 25- and 16-kDa proteins of the photosynthetic oxygen-evolving complex protein).[751] Use of the refined *in vitro* import system indicates that there may be distinct translocation systems involved in the transport of proteins across the thylakoid membrane, each recognizing specific features in the presequences of a subset of luminal proteins (see later discussion).

Cytochrome f is an example of a chloroplast-encoded protein that is targeted to the thylakoid membrane system; its transport is presumed to be functionally equivalent to that of imported stromal intermediates *en route* to the thylakoids. Following its synthesis in the stroma on thylakoid-bound ribosomes, the precursor inserts partially into the thylakoid membrane by a C-terminal stop-transfer domain; a transient N-terminal sequence is then removed following membrane insertion.[752]

C. Protein Targeting to the Envelope Membranes and Intermembrane Space

In comparison with the targeting of proteins to the stroma and thylakoids, much less is known about the targeting of chloroplast envelope proteins, in part because of their low quantities compared with other chloroplastic proteins. None of the outer envelope membrane proteins studied so far (e.g., 6.7- and 14-kDa proteins from spinach and pea, respectively) has a cleavable transit peptide.[753,754] Thus, proteins destined for the outer membrane of the chloroplastic envelope are likely to follow an import pathway distinct from that followed by proteins destined for other chloroplastic compartments, and the necessary information is most likely located within the mature protein (Figure 33), although its precise nature remains to be determined. The targeting of these proteins is unique in other ways; for example, it does not require ATP or a protease-sensitive receptor.[704]

By contrast, import studies with different inner membrane proteins (e.g., a 37-kDa protein and a phosphate translocator, both from spinach) indicate the presence of cleavable transit peptides.[755,756] Studies on the maize *bt-1*-encoded protein indicate that the transit peptides of inner membrane proteins function primarily as stromal targeting sequences; the specific information for subsequent targeting to the inner envelope is contained in the mature region of the protein.[757]

The components of the intermembrane space remain elusive. No proteins of this compartment have been identified, due in part to the inability to biochemically distinguish the intermembrane space from the stroma using current techniques.[704]

D. Energy Requirements

Energy is required for both protein translocation across the chloroplast envelope and for efficient binding of precursors to the outer envelope membrane.[758,759] Hydrolyzable nucleoside triphosphate (NTP) in the intermembrane space likely drives the binding of precursors to the outer-envelope receptor.[759,760] The site of NTP hydrolysis, the specificity of the requirement for NTP and the apparent K_m of the reaction distinguish the ATPase that mediates the binding reaction from what drives the translocation of bound precursor across the envelope membranes.[704,758–761] Hydrolyzable ATP (inside the chloroplast stroma) is the energy source utilized for translocation;[758] required concentrations for translocation are approximately five- to tenfold higher than those necessary for binding. Neither the electrical nor chemical components of a PMF are involved in translocation across the envelope membranes in chloroplasts.[758]

Efficient integration of LHCP into the thylakoid membrane requires energy;[734,762,763] as mentioned earlier, this requirement can be met by ATP alone, but the presence of a PMF across the thylakoid membrane in addition to ATP renders the process more efficient. Energy is also required for translocation across the thylakoid membrane into the lumen;[764] however, different precursors utilize different forms of energy for the translocation reaction[765,766] (reviewed in References 704 and 706) (Figure 34). This has led to the suggestion that thylakoid transfer signals direct translocation across the thylakoid membrane by two distinct mechanisms mediated by two distinct translocases in the thylakoid membrane.[706,766] As shown in Figure 34, precursors are imported into the stroma, probably by a common mechanism that requires ATP. From the stroma, translocation across the thylakoid membrane may occur via distinct pathways; translocation of plastocyanin and the 33-kDa subunit of the oxygen-evolving complex requires at least one stromal factor and ATP, but can take place in the absence of a PMF (the ΔpH component).[742,766] In contrast, translocation of the 23- and 16-kDa subunits of the oxygen-evolving complex requires only a ΔpH across the thylakoid membrane, with no requirement for ATP.[706,766] A third pathway is followed by the integral thylakoid protein, CF_0II (subunit II of the ATP synthase complex), whose insertion into the thylakoid membrane does not require stromal factors, ATP, or the ΔpH.[767] A spontaneous integration mechanism has been invoked for this protein (reviewed in Reference 706). Studies to deter-

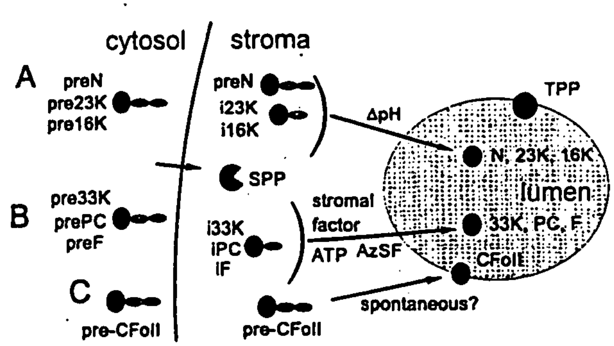

FIGURE 34. Multiple mechanisms of thylakoidal protein translocation. The six luminal proteins shown, and the integral membrane protein CFoII are synthesized with bipartite presequences and imported into the chloroplast, probably by a common mechanism. In the stroma, all of the precursors except pre-PSI-N and pre-CFoII are cleaved to intermediate forms by SPP. Further targeting into the thylakoids involves the operation of three distinct pathways. Translocation of PSI-N, 23K, and 16K across the thylakoid membrane appears to require only the thylakoidal ΔpH (pathway A), whereas translocation of 33K and PC is dependent on the presence of a stromal factor, ATP, and an azide-sensitive factor (AzSF); it is possible that the AzSF corresponds to the stromal translocation factor. The role of stromal factors and ATP in PSI-F translocation is not yet known, but this protein has been grouped with 33K and PC (pathway B) because translocation is sensitive to azide, does not require the thylakoidal ΔpH, and does not compete with that of 23K. A third pathway (C) is followed by the integral protein, CFoII, whose insertion into the thylakoid membrane does not require stromal factors, ATP or the ΔpH. After translocation into or across the thylakoid membrane, all of the proteins are apparently cleaved to the mature size by a common thylakoidal processing peptidase, TPP. (From Robinson, C. and Klösgen, R., *Plant Mol. Biol.*, 26, 15, 1994. With permission from Kluwer Academic Publishers.)

mine whether the different energy and stromal factor requirements reflect different translocation machineries in the thylakoid or whether a common translocation apparatus can operate in different energy-coupled modes[704] are awaited with interest.

E. Precursor Binding and the Identification of Receptors and Accessory Proteins

The first step in the transport of precursor proteins into chloroplasts is a specific interaction between the precursor and outer envelope membrane; the components that mediate this binding, as well as subsequent translocation, are likely to involve both membrane lipids and intrinsic proteins.[702] There are several lines of indirect evidence for receptor-mediated binding. For example, studies showing diminished binding of precursors following protease (thermolysin) treatment, which specifically destroys outer membrane proteins, indicate that a protein component(s) of the chloroplast outer envelope is necessary for high-affinity binding of precursors.[768,769] Moreover, precursor binding is ligand-specific; chloroplastic proteins lacking transit peptides do not bind to chloroplasts. Likewise, binding is membrane-specific; chloroplastic precursors generally do not bind to nonchloroplast membranes (e.g., plasma membranes and erythrocyte membranes) (see Reference 702 and references therein). Several other characteristics of precursor binding are indicative of receptor involvement (e.g., binding sites are limited and saturable; binding is rapid, specific, and requires energy in the form of ATP).[759,769,770] Saturation experiments led to an estimate of 1500 to 3500 binding sites (receptors) per chloroplast (reviewed in Reference 704).

At present, very little is known about the nature and composition of the translocation machinery. Translocation is thought to occur at regions where the inner and outer envelope membranes are closely appressed in so-called contact sites.[704,711] These sites may be dynamic structures, possibly formed as a consequence of protein translocation (reviewed in Reference 704). Several proteins that may be components of the signal recognition and transport apparatus have been identified. A heterobifunctional photoactivatable cross-linking reagent was used to implicate a 66-kDa chloroplast surface protein.[772] Experiments utilizing anti-idiotypic antibodies (in this case, antibodies capable of recognizing other antibodies specifically directed against a synthetic analog of the SSU-Rubisco transit peptide) have identified a putative (30-kDa) import receptor, apparently located at contact sites between the outer and inner envelope membranes.[773,774] However, recent work suggests that this protein is identical to the phosphate-3-phosphoglycerate-phosphate translocator,[775,776] suggesting a more indirect role in targeting.

ATP-dependent phosphorylation of a 51-kDa envelope protein is correlated with precursor translocation into chloroplasts.[777] However, whether it plays an integral role in the import process per se is unknown. Another approach for identifying putative transport components is to bind precursors to isolated outer membranes and then solubilize the membranes with detergent to identify a complex that remains associated with the bound precursor. Ten outer envelope proteins cosediment in a sucrose gradient with bound precursor SSU-Rubisco, including an 86-kDa protein, a Hsc70 protein, and a 34-kDa protein;[705,778] the complex isolated from the outer membrane can interact with precursor proteins.[779] More recently, a label transfer cross-linking reagent has been used to identify putative components of the transport apparatus;[780] the cross-linking was performed using precursor to the SSU-Rubisco that was blocked at an early stage of the transport process. In this approach, the cross-linker is cleavable, leaving the putative transport component modified with the radiolabeled portion of the cross-linker. Two envelope proteins were identified — an 86-kDa protein and a 75-kDa protein — both components of the outer membrane. Low levels of ATP stimulate labeling of the 75-kDa protein, whereas labeling of the 86-kDa protein is ATP-independent. The authors propose that precursors initially bind in an ATP-independent fashion to the 86-kDa protein; the energy-requiring step is associated with the 75-kDa protein and assembly of a translocation contact site between the inner and outer membrane of the chloroplastic envelope.[780] Protein-lipid interactions may also be involved in the initial binding of precursors to the chloroplast outer membrane; for example, they may mediate both the initial membrane insertion as well as facilitate transit peptide interaction with specific receptor proteins at the membrane surface.[702]

The role of molecular chaperones in the translocation process has been investigated; in carrying out their role, these proteins may reside on both sides of the membrane (reviewed in Reference 705). Hsp70 homologs have been identified within chloroplasts,[781,782] but their specific functions are not known. In higher plants, they are localized to the envelope[783] and stroma.[784,785] As mentioned earlier, proteins of the Hsp70 family are believed to prevent precursors from assuming a transport-incompetent conformation in the cytosol. However, a requirement for soluble factors in chloroplast protein import may be precursor specific, and little is known about the protein conformational changes that take place during precursor binding and import into chloroplasts. Some precursors of soluble stromal proteins are fully competent for import in the absence of cytosol (reviewed in Reference 704); other proteins such as LHCP may require cytosolic molecular chaperones to maintain an import-competent state.[786] Dihydrofolate reductase (DHFR) fusion proteins have been useful for studying conformational changes during protein import.[787,788] Folate analogs such as methotrexate bind tightly to DHFR and stabilize its mature folded conformation. This compound strongly inhibits the import of DHFR into yeast mitochondria,[789] presumably because the precursor must unfold to cross the membrane and is prevented from doing so when complexed

with methotrexate. In contrast, DHFR fusion proteins unfold despite the presence of methotrexate on binding to the chloroplast envelope. These results tend to support the existence of a strong protein unfolding activity associated with the chloroplast envelopes.[787,788] The role of chaperones located in the stroma in chloroplast protein import still needs to be fully addressed. The Reiske-Fe protein (a thylakoid membrane protein) becomes associated, in an ATP-dissociable form, with an Hsp70 homolog in the chloroplast stroma;[790] formation of a complex between the precursor and Hsp60 precedes the Hsp70 association. Recently a chloroplast homolog of the SRP (54-kDa subunit) has been identified in *Arabidopsis* that may play a role in intraorganellar targeting.[791] As noted earlier, several parallels exist between the targeting of chloroplast-encoded proteins to the thylakoids and the targeting of secretory proteins to the ER.

F. Assembly of Oligomeric Protein Complexes: Role of Chaperonins

As mentioned earlier, the synthesis and assembly of Rubisco involves the interaction of two genetic systems viz., nuclear and chloroplastic. The LSUs of Rubisco are synthesized within the chloroplast; the nuclear-encoded small subunits are imported after synthesis in precursor form on cytosolic polyribosomes.[707] The assembly of the holoenzyme (which in its mature assembled form consists of eight subunits of each type) occurs within the stromal compartment, and appears to require the presence of another protein, the Rubisco subunit binding protein, more recently termed the chloroplast chaperonin (cpn) (reviewed in References 792 through 794). This protein binds noncovalently to both newly synthesized LSUs and to imported small subunits. Convincing evidence for its role in assembly processes is available; for example, antiserum to the binding protein inhibits the transfer of newly synthesized Rubisco LSUs to the holoenzyme in stromal extracts (see Reference 792 and references therein). A representative of the chaperonin 60β gene family of *Arabidopsis* is both developmentally regulated and repressed by wounding when expressed in transgenic tobacco.[795] Interestingly, cpn is related to the GroEL protein of *Escherichia coli*, a heat-shock protein that is essential for cell growth[796] and bacteriophage assembly.[797] In addition, GroEL is required for assembly of prokaryotic Rubisco synthesized in *E. coli*[798] and it may also be involved in protein secretion.[799,800] Growth and development of transgenic tobacco plants transformed with the *E. coli groEL* gene are indistinguishable from control plants.[801] A second class of chaperonins (the 10-kDa class, Cpn10, equivalent to GroES in bacteria) has been identified recently in *Arabidopsis*.[802] Similar to the functions of the ER-resident molecular chaperones (discussed earlier), the cpns are proposed to assist other polypeptides in maintaining or assuming a conformation required for their correct assembly, possibly via their ATPase activities.[792,803] This role is not limited to the assembly of Rubisco; rather, the chloroplast chaperonin appears to be involved in the assisted assembly and/or folding of a wide range of proteins in chloroplasts.[804,805] Similar chaperonin-type proteins (e.g., Hsp60) have been implicated in oligomeric protein assembly in mitochondria (see later discussion). Thus, assisted assembly of oligomeric protein structures is emerging as a general cellular phenomenon and is an important aspect of regulation of gene expression at the posttranslational level.[792]

X. PROTEIN TARGETING INTO AND WITHIN MITOCHONDRIA

Mitochondria fulfill a variety of essential metabolic functions; in particular, as a major site for oxidative phosphorylation, they are often referred to as the "powerhouse" of the cell. The mitochondrial subcompartments each have a characteristic set of polypeptides and include the outer membrane, the intermembrane space, the inner membrane, and the matrix (Figure 32). Like the chloroplast, the great majority of mitochondrial proteins (i.e., greater than 90%) are contributed by the nucleocytosolic system.[806] Precursor synthesis on free polyribosomes of the cytosol is followed by posttranslational import into the organelle.[807,808] Much of our current understanding of the events required for organelle assembly and

mechanisms of mitochondrial protein transport has derived from *in vivo* and *in vitro* studies in animals, yeast, and *Neurospora* (reviewed in References 809 through 813). Much less information is available on mitochondrial protein transport in plants; however, some of the general principles derived from studies of other eukaryotic systems may also prove to be applicable to plants.

A. Protein Targeting to the Matrix

Proteins that are destined for the mitochondrial matrix (as well as most of those which will ultimately reside in the inner membrane or intermembrane space) are synthesized as precursors containing targeting sequences (termed "presequences") of 10 to 70 amino acids. In most cases (but not all),[814,815] these cleavable presequences are located at the N-terminus of the precursor. Much like the transit peptides of chloroplast precursors, sequence homology among mitochondrial presequences is lacking; common features include a high proportion of positively charged and hydroxylated residues and a general paucity of acidic amino acids.[816,817] Moreover, they also possess a high degree of autonomy, being both necessary and sufficient to direct nonmitochondrial passenger proteins into the mitochondrial matrix.[818,819] Recently, this has been shown for plant mitochondrial presequences in transgenic tobacco plants. The presequence of the mitochondrial β-subunit of F_1ATPase ($F_1\beta$) (from tobacco) is capable of directing the bacterial protein CAT into mitochondria, with high organellar specificity.[820] Likewise, the N-terminal 60 residues of the $F_1\beta$ presequence are sufficient for transport of cytosolic glutamine synthase (of *Phaseolus vulgaris*) to the mitochondria in transgenic tobacco.[821] When GUS is linked to the presequence of the δ-subunit of F_1ATPase (from sweet potato), the chimeric protein is efficiently transported into mitochondria only if the N-terminal regions of the mature protein are also present.[822] The nuclear-encoded precursor of mitochondrial superoxide dismutase (SOD isozyme 3, a manganese-containing homotetrameric enzyme) is translocated into isolated maize mitochondria. Deletions in the presequence of maize SOD-3 (generated *in vitro*) show relative import efficiency to be highly correlated with deletion size.[823]

A yeast mitochondrial presequence is capable of targeting a foreign protein into plant mitochondria *in vivo*.[824] The fusion protein consisted of the presequence of yeast mitochondrial tryptophanyl t-RNA-synthetase linked to GUS; specific targeting and efficient import into the mitochondria of transgenic tobacco cells occurred, with no substantial misrouting. Proteolytic processing of the precursor was equivalent in the two eukaryotic systems, with respect to both precision and fidelity; thus, the processing enzyme in plant mitochondria appears to recognize the same cleavage site within the presequence as the matrix protease from yeast.[824]

It appears then, that the targeting of chimeric proteins is organelle-specific; dual targeting into mitochondria and chloroplasts is not a general phenomenon. Exceptions do exist, however. For example, a yeast mitochondrial presequence (linked to a bacterial passenger protein) is recognized and can interact functionally with the protein translocation systems of both chloroplasts and mitochondria in transgenic tobacco.[825]

It is generally assumed that the essential feature of the presequence in the binding/translocation process is encrypted in a specific secondary or tertiary conformation (rather than in specific amino acid residues). Many targeting signals of mitochondrial precursors have the potential to form amphiphilic α-helices and β-sheets (i.e., secondary structural arrangements with the polar and nonpolar residues exposed to opposite faces).[729,730,826] Such structures are said to have a hydrophobic moment,[827] and react spontaneously with the surfaces of biological membranes.[828] This amphiphilicity is proposed to be important for the initial membrane insertion and/or the interaction with specific receptor proteins at the mitochondrial surface.[811]

Most protein translocation into mitochondria occurs at sites where the outer and inner membranes are in close proximity.[829] It proceeds through a hydrophilic (proteinaceous) membrane environment; protein-lipid interactions may also occur.[830] The translocation complex seems to consist of two distinct translocation channels in the outer and inner membranes (see later discus-

sion).[813,831] Once translocated across the mitochondrial membranes, the N-terminal presequences of precursors are cleaved by a highly specific metal-dependent processing enzyme in the matrix.[832] This proteolysis is not coupled to membrane translocation, but is an essential process (e.g., in yeast),[833] probably being required for proper assembly of imported proteins.[811] Proteolytic processing is thought to be a cooperative effort requiring two structurally related components that may recognize different structural elements of presequences, and hence, contribute to the high specificity of cleavage. One component may bind to presequences of incoming proteins (in a cotranslational manner), thus exposing the cleavage site towards the other component.[811,834] In the mitochondria of lower eukaryotes and mammals, the general processing peptidase consists of two subunits, α-MPP and β-MPP, both located in the matrix[808,834,836–838] (reviewed in Reference 835). In *Neurospora*, the β-MPP is primarily membrane-associated, although the active part of this subunit is located in the matrix.[839] In potato and spinach, the processing enzyme is an integral part of the bc_1 complex;[840,841] processing activity of spinach leaf mitochondria is membrane bound.[842] There may be three components of the mitochondrial processing enzyme of potato.[840] Interestingly, there are tissue-specific differences in the activity and solubility of the general processing enzyme in mitochondria of spinach leaves vs. roots; two populations of the processing peptidases may be present in root mitochondria.[843]

B. Protein Targeting to the Inner Membrane and Intermembrane Space

Proteins residing in the matrix reach their target compartment by translocation across the two membranes at contact sites; additional routing is required for correct localization of proteins of the inner membrane or intermembrane space. Soluble proteins of the intermembrane space (e.g., cytochrome b_2 of yeast mitochondria) as well as cytochrome c_1 of the bc_1 complex (which is largely exposed to the intermembrane space) are synthesized as cytosolic precursors with long complex presequences[844–846] having a bipartite structure. Their N-terminal parts exhibit the typical features of presequences of matrix-targeted proteins (and are functionally equivalent); the remaining C-terminal parts contain numerous hydrophobic residues preceded by one to four basic residues. This latter motif is thought to direct "export" of intermembrane proteins from the matrix back across the inner membrane.[847,848] However, another view is that it functions as a stop-transfer signal. According to the stop-transfer hypothesis, the N-terminal part of the presequence is imported into the matrix, but the intermembrane space targeting domain arrests further translocation through the inner membrane (reviewed in Reference 813). The composite presequences undergo cleavage in two steps executed by different processing peptidases: the matrix α-MPP/β-MPP and a membrane-associated peptidase at the outer surface of the inner membrane (IMP I, inner membrane peptidase).[835,847,849–851] Cytochrome c_1 from potato also contains a transient presequence with a bipartite structure comparable to that described for the fungal proteins;[840] the targeting mechanism of the plant protein has not yet been determined.

The Rieske Fe-S protein is a peripheral component of the bc_1 complex located at the outer surface of the mitochondrial inner membrane; in yeast and *Neurospora*, the protein reaches its functional location on an import route via the matrix.[811,852,853] However, the presequence lacks a hydrophobic segment and contains information for targeting to the matrix only; information for its subsequent relocation to its final destination may be encoded in the mature protein.[854,855] Proteolytic processing is in the matrix only, and occurs via a two-step mechanism. The Reiske Fe-S protein of potato shares about 50 and 43% sequence identity with the same proteins from fungi and mammals, respectively.[856] The plant protein is made as a larger precursor of 30 kDa; its presequence of 53 amino acids has molecular features different from those found in presequences of fungal iron-sulfur proteins. Further, unlike in yeast and *Neurospora*, the presequence of the plant protein is removed by a single processing step.[856]

It is noteworthy that there are a few proteins of the mitochondria whose assembly and transport pathways are unique and do not conform to conventional intramitochondrial targeting routes (i.e., rerouting following transport into the matrix).[811] The ADP- and ATP-carrier (AAC) of the inner membrane (and possibly some other structurally-related proteins) are examples. The cytosolic precursor of AAC is made without a cleavable presequence;[814] targeting information resides in three internal segments.[857] Following its entry into the outer membrane (and subsequent transport into contact sites), there is lateral diffusion into the inner membrane. The signals that prevent translocation into the matrix and trigger integration into the inner membrane are unknown.[811] Cytochrome c also does not follow a reexport pathway; it reaches the intermembrane space by crossing the outer membrane only.[858,859]

C. Other Components Involved in Protein Import and Assembly

Several of the components of the mitochondrial import machinery have been identified recently, mostly in *Neurospora crassa* and in the yeast *S. cerevisiae*. These include (1) cytosolic cofactors, particularly chaperone components; (2) import receptors and accessory components of the outer membrane; (3) components of the translocation machinery of the inner membrane; and (4) the matrix heat-shock proteins Hsp70, Hsp60, and their partners (reviewed in Reference 809) (Figure 35).

Precursor proteins must be maintained in a loosely folded conformation after synthesis, for their subsequent efficient translocation across mitochondrial membranes.[860–862] Constitutively expressed heat-shock proteins of the Hsp70 family have been implicated in the stabilization of precursors in a translocation-competent state; by binding to precursors cotranslationally, they may help to keep targeting signals exposed.[107,124,863–867] A NEM-sensitive factor associated with the cytosolic surface of mitochondria also appears to play a cooperative, facilitative role; along with ATP, it is required for the release of proteins from Hsc70.[868,869] As mentioned earlier, the translocation complex consists of two distinct translocation channels in the outer and inner membranes (Figure 35).[809,870] The first specific step of the import pathway is the binding of precursors to the surface of the mitochondrial outer membrane.[871,872] In *Neurospora*, two outer membrane receptor/binding proteins (MOM19 and MOM72 — 19 and 72 kDa, respectively) have been identified.[873] Inhibition of precursor binding and import by antibodies recognizing the cytosolic domains of the proteins is indicative of their role as receptors that participate in the specific recognition of precursors; also significant is the observation that these proteins are enriched in the outer membrane at contact sites between inner and outer membranes, where most translocation takes place.[873] The subsequent entry of precursors into the translocation apparatus is thought to be facilitated by a common (integral) component in the outer membrane, the general insertion pore (GIP) (Figure 35) (see Reference 870 and references therein). Four subunits (MOM38, MOM30, MOM8 and MOM7) may constitute the GIP. These are in close proximity to precursors arrested in the GIP and presumably contribute to formation of the pore. Yet another component may be needed for the transfer of preproteins from the surface-exposed receptors MOM19 and MOM72 to the membrane-embedded components of the GIP. This appears to be the role of MOM22 — a central component of the receptor complex whose negatively charged domain (exposed to the cytosol) may allow it to interact with and transfer the positively charged presequences on preproteins (Figure 36).[870] Proteins of the matrix, inner membrane, and intermembrane space may be routed from the GIP into contact sites for further translocation; precursors of outer membrane proteins (e.g., porin) may also insert into their target membrane directly via the GIP.[811]

After translocation of precursors through the mitochondrial innermembrane import machinery (MIM), the presequence is proteolytically removed in the matrix, and proteins destined to reside in the matrix are folded into their functional forms (Figure 36). Current models envision that the import systems of the outer and inner membranes can be transiently linked by translocating polypeptide chains,[831] thereby forming translocation contact sites.[829] Thus, the two transport machineries are not permanently connected. Further, translocation of preproteins across the outer membrane

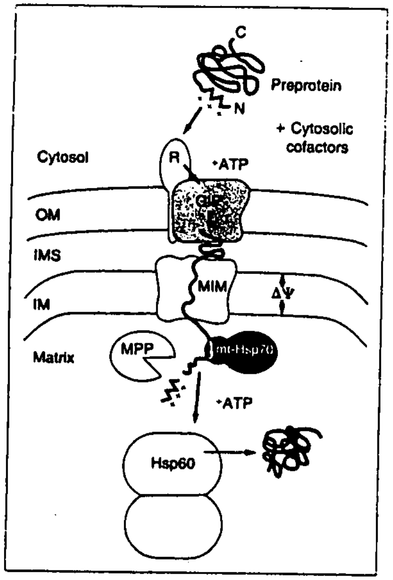

FIGURE 35. Basic scheme of mitochondrial protein import. The transport pathway of a preprotein into the mitochondrial matrix is shown. The preprotein typically carries a positively charged presequence at its amino terminus (N). Cytosolic cofactors prevent misfolding or aggregation; some of them function in an ATP-dependent manner. The preprotein binds to a receptor (R) and is translocated across the outer membrane (OM) through the general insertion pore (GIP). Translocation across the inner membrane (IM) is mediated by the mitochondrial inner membrane import machinery (MIM), and requires a membrane potential (ΔΨ). In the matrix, the heat-shock protein Hsp70 binds to the preprotein; the mitochondrial processing peptidase MPP cleaves off the presequence, and the protein is folded, aided by Hsp60. Both heat-shock proteins require ATP. The outer- and the inner-membrane machineries are not permanently connected by a sealed channel, but a preprotein in transit across the membranes contacts the intermembrane space (IMS). However, the outer- and inner-membrane machineries can be transiently connected by a preprotein spanning both membranes. C, carboxyl terminus. (From Pfanner, N., Craig, E. A., and Meijer, M., *Trends Biochem. Sci.*, 19, 368, 1994. With permission from Elsevier Publishing, Cambridge.)

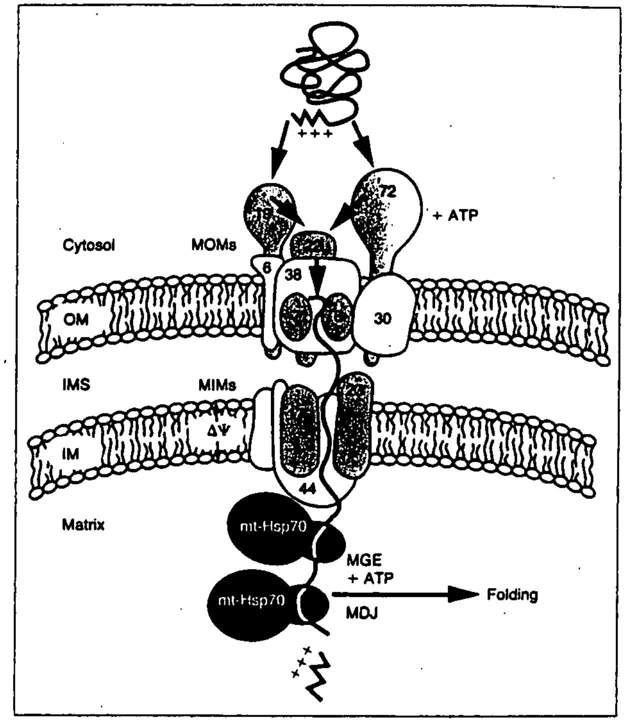

FIGURE 36. Hypothetical model of the protein-import machineries in the mitochondrial membranes. The mitochondrial outer membrane (MOM) machinery consists of at least eight different proteins: the import receptors MOM19 and MOM72 (MOM proteins of 19 and 72 kDa, respectively); the transfer component MOM22; the general insertion pore (GIP) with MOM38, MOM30, MOM8, and MOM7; and ISP6, which was shown to interact genetically with MOM38/ISP42. The integral membrane proteins MIM17 and MIM23 and the preprotein-binding protein MIM44 are components of the mitochondrial inner-membrane import machinery (MIM). The mitochondrial Hsp70 (mt-Hsp70) also binds the polypeptide chain in transit. Mt-Hsp70 is assumed to interact with MGE and MDJ, the mitochondrial homologs of the prokaryotic heat-shock proteins GrpE and DnaJ. Interaction of the positively charged presequence with the MIM machinery requires a membrane potential, (ΔΨ). IM, inner membrane; IMS, intermembrane space; OM, outer membrane. (From Pfanner, N., Craig, E. A., and Meijer, M., *Trends Biochem. Sci.*, 19, 368, 1994. [Also see references therein.] With permission from Elsevier Publishing, Cambridge.)

is independent of the membrane potential ($\Delta\Psi$); in contrast there is a strict requirement for a $\Delta\Psi$ for translocation across the inner membrane.[809,874] Three MIM proteins are essential components of the import machinery in yeast and *Neurospora* (reviewed in Reference 809) (Figure 36). Two of these components (MIM17 and MIM23/MAS6) are thought to form part of a channel. The third essential component, MIM44, in cooperation with the heat-shock protein Hsp70, binds the preproteins in transit. The latter (i.e., matrix-Hsp70) plays a dual role in the translocation process.[875–877] First, by binding directly to the preprotein, it facilitates the stepwise unfolding of the remainder of the polypeptide chain on the outside of the outer membrane by trapping preprotein segments emerging on the matrix side (unfoldase function). Second, it is essential for the complete import of preproteins into the matrix, independent of their folding state (translocase function). In cooperation with the mitochondrial homologs of bacterial DnaJ and GrpE, Hsp70 forms an initial part of the machinery for folding imported proteins by transferring them to Hsp60 (see below)[809] (Figure 36). The MIM machinery is likely not a static channel; rather, the MIM proteins and their partners, such as the matrix Hsp70, may assemble and disassemble in a dynamic manner.[809] Both an electrical membrane potential and ATP are needed to drive protein translocation through the MIM import machinery.[809] The membrane potential, $\Delta\Psi$, triggers the translocation of the initial part of the preprotein, the N-terminal presequence, across the inner membrane.[878] ATP in the matrix is needed to complete the translocation of the presequence and to allow translocation of the mature portion into the matrix rendering the import process irreversible.[271,864,875,877] Although part of this ATP requirement is due to the ATP-dependent action of the matrix-Hsp70, further components of the import machinery are likely to require ATP to function.[809] Hsp60 (a large protein complex located in the matrix) plays an integral role in protein folding and assembly *in vivo*.[792,811,879–881] This protein may have several functions. It mediates the ATP-dependent folding of imported matrix proteins; folding may be prevented until the complete polypeptide is available.[880] A role in the maintenance of a translocation-competent state is also suggested, particularly for imported proteins that must undergo further intraorganellar targeting (e.g., insertion into, or translocation across, the inner membrane).[879] Finally, Hsp60 of the mitochondrial matrix is highly homologous to the GroEL protein of *E. coli* and to the Rubisco-binding protein of chloroplasts, and is also a member of the subgroup of molecular chaperones termed "chaperonins" (see earlier discussion). Thus, related to its role in mediating protein folding (e.g., recognizing structural motifs in unfolded or loosely folded polypeptide chains and repairing misfolded proteins), Hsp60 may also play an essential role in the assembly of large oligomeric proteins in the matrix.[792]

XI. PROSPECTS FOR ENGINEERING CHLOROPLAST AND MITOCHONDRIAL PROTEINS

A recent focus of genetic engineering in plants has been toward the ultimate development of systems for influencing the efficiency of plant growth and carbon fixation by photosynthesis, as well as the engineering of herbicide tolerance. This has involved the use of many novel approaches, including the manipulation of genes encoding important proteins (e.g., key enzymes of metabolic pathways) coupled with the exploitation of targeting mechanisms of proteins within both cells and organelles.

A. Herbicide Tolerance

Genetic engineering of herbicide tolerance into crop species is of significant interest to agricultural biotechnology. Particular interest in engineering tolerance to the herbicide glyphosate (*N*-[phosphono-methyl] glycine) stems from some of its desirable properties (e.g., its nontoxicity to animals and rapid degradation by soil microorganisms).[882] This herbicide functions by inhibiting the enzyme 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase, and thus prevents plant growth by blocking the pathway of aromatic amino acid synthesis.[883] Some degree of tolerance to this herbicide has been achieved by introducing into host plants a bacterial EPSP synthase gene (that encodes a resistant enzyme). To direct correct chloroplastic localization of this mutant enzyme form, the DNA encoding the plant EPSP synthase transit peptide was linked to the bacterial enzyme coding region. The *in vitro* product of this chimeric gene is rapidly imported into chloroplasts, where it accumulates as a stable, glyphosate-resistant enzyme.[722] Another strategy has been to introduce a plant EPSP synthase gene under the control of the cauliflower mosaic virus (CaMV) 35S promoter; in this case, the inhibitory effect of glyphosate is counteracted by overproduction of the plant enzyme targeted to the chloroplast by its own transit peptide.[884]

A further approach to the engineering of herbicide tolerance involves a recent technology developed for the conversion of chloroplast (and mitochondrial) genes into nuclear genes and for the subsequent retargeting of the cytosolically synthesized protein into its respective "home" organelle (reviewed in Reference 885). This effective relocation of genes from organelle to nucleus mimics the natural events proposed to have occurred during evolution (i.e., the relocation of the majority of genes from an endosymbiotic organism to the host cell nucleus). Reformatting organellar genes for this "allotopic" expression (i.e., expression in a foreign or alien environment) involves several manipulations, including:

1. Changing the open reading frame of the organellar gene (e.g., so that codon usage is compatible with the biases of the nucleo-cytosolic system).
2. Placing the open reading frame within a suitable nuclear transcription context (including appropriate promoter and terminator); a functional nuclear replicator sequence is provided to ensure the replication and maintenance of the restructured gene in the nucleus.
3. Addition of DNA encoding a N-terminal leader sequence to ensure correct targeting of the fusion protein into its home organelle, subsequent to its synthesis in the cytosol.

This strategy has been used in attempts to engineer resistance to the triazine herbicides (e.g., atrazine). The triazine group of herbicides compete with thylakoid plastocyanin for binding with the quinone-binding protein (Q_B of photosystem II) and, thus, interrupt photosynthetic electron flow.[886] In thylakoid membranes, the Q_B protein of atrazine-sensitive plants, including the weed *Amaranthus hybridus*, binds azidoatrazine; Q_B protein from an atrazine-resistant biotype does not bind the herbicide because of a single amino acid residue substitution.[887] The allotopic expression of the resistant form of Q_B protein from *Amaranthus* has been achieved in host tobacco cells.[888] The coding region of the donor (resistant) gene (*psbA*) was fused to the promoter and transit-peptide-encoding sequences of the SSU-Rubisco gene, and the chimeric gene was introduced into tobacco plants. The transgenic tobacco plants were tolerant to levels of atrazine that are toxic to nontransformed plants, although the atrazine-resistant phenotype was not sustained for long periods of plant growth.[888] Because expression of the endogenous ("sensitive") gene was not blocked in these plants, the variant Q_B protein was delivered to the organelles in which normal levels of the naturally encoded protein were produced. Thus, the transformants contained a mixed population of photosystem II complexes. Nonetheless, correct targeting of the variant Q_B form to the chloroplast could be demonstrated (by immunocytochemical means), and the recovery of atrazine-tolerant transgenic plants shows that the protein functions in photosynthesis.[888]

B. Increasing Photosynthetic Productivity

Rubisco catalyzes the first step in the processes of both photosynthesis and photorespiration; because it is the balance between these two processes that ultimately controls plant productivity, this enzyme is a major target for genetic engineering (e.g., mutagenesis), with the aim of altering this balance for agricultural purposes.[889] Toward this goal, expression of Rubisco in a prokaryotic host has been undertaken.[792] Until recently, little success has been achieved, in part due to a failure of Rubisco subunits to assemble properly in the bacterial host; hence, an enzymatically active form is not produced.[792,890] Assembly may not occur because the chaperonins of these bacterial host cells, which would normally medi-

ate protein assembly, are sufficiently different from those of plant cells, and hence, are nonfunctional in Rubisco assembly. Thus, a current aim is to express the cDNAs for the chloroplast chaperonin in the same *E. coli* cells that are expressing the genes for Rubisco from higher plants. In this way, Rubisco assembly should be rescued, permitting attempts to improve the properties of this agriculturally important enzyme.[792]

Allotopic expression of the LSU of Rubisco has been achieved in *Oenothera hookeri* (evening primrose) (see Reference 885 and references therein). The transit peptide and transcriptional control sequences from the pea SSU-Rubisco gene were utilized for nucleocytosolic expression; the host was a plastome mutant containing a sigma mutation[891] in the Rubisco LSU (*rbcL*) gene of chloroplast DNA. Hence, the mutant expresses only a truncated version of the LSU. Allotopic expression of full-length LSU was achieved, curing the sigma phenotype in transformants.

Because the technology of allotopic expression allows both controls over quantitative expression of the engineered gene and the subsequent correct delivery to the organelle of a protein of defined structure, it should have significant potential as a novel approach for basic investigation into the biogenesis, assembly, and function of a number of enzyme complexes in the chloroplast.[885] Its potential as a natural assay system for directly manipulating photosynthetic productivity (e.g., via changes to Rubisco subunits to diminish photorespiration and enhance CO_2 fixation) may also be exploited in the future.

C. Allotopic Expression of Mitochondrial Genes

This strategy may also prove to be useful for similar basic and applied studies of mitochondrial-encoded proteins. Successful allotopic expression of at least two mitochondrial genes has been achieved in yeast.[885] For example, expression of a yeast gene encoding subunit 8 of mitochondrial ATPase was demonstrated in mutant host cells unable to synthesize the endogenous mitochondrial protein; transit peptide sequences (derived from the mitochondrial *Neurospora* subunit 9 gene) effected the required mitochondrial import.[892] In a similar manner, another mitochondrial gene (for the intron-encoded maturase of cytochrome b) was expressed allotopically in yeast cells.[893]

Thus, there appears to be no intrinsic biological barrier to chloroplast or mitochondrial genes being encoded in the nucleus; the subsequent import of the synthesized protein into the target organelle is also possible, provided an appropriate presequence or transit peptide is utilized.[885] Other approaches to the manipulation and analysis of organellar genes could potentially make use of current techniques for direct delivery of organellar DNA into mitochondria and chloroplasts (e.g., via projectile techniques, polyethylene glycol [PEG] treatment, or possibly via DNA-protein conjugates).[894–898] Although these approaches may have a more limited potential than allotopic expression strategies,[885] future attempts to engineer organellar genes and their encoded protein products may exploit a combination of these avenues.

XII. SUMMARY

It is apparent that posttranslational controls are an important aspect of the regulation of gene expression in all eukaryotes. Studies on the mechanisms of protein targeting in plant cells have progressed markedly in the last 5 years; however, in certain areas, much more information is presently available in other eukaryotic systems. Although important exceptions exist, a striking feature of the mechanisms and cellular machinery of protein targeting is their universality — among animals, plants, and eukaryotic microorganisms — and even between prokaryotes and eukaryotes. Mechanisms of vesicle targeting and the role of GTPases will very shortly become a rapidly developing aspect of plant cell biology. Studies have also progressed toward characterizing signals involved in the transport and targeting of proteins to the nucleus, chloroplast, mitochondrion, peroxisome, and glyoxysome. The recent refinement of methods for subcellular localization of specific proteins (and their corresponding transcripts) will aid further progress in this area.[899] The specificity of protein-targeting processes is the very basis of maintaining structural and functional integrity of the cell, enabling the various subcellular compartments to carry out their diverse metabolic roles.

Protein stability may also be influenced by subcellular localization; various factors appear to contribute to a protein's half-life in the cell. One of these is the ability of the protein to undergo normal folding and assembly processes and to assume a functional three-dimensional structure; failure to achieve this results in the activation of the cell's disposal mechanisms to remove nonfunctional proteins or components. A consideration of these factors also has far-reaching implications for applied studies geared toward the genetic engineering of plants for agronomically useful traits or characteristics, in particular, where success will depend on achieving high levels of accumulation of a foreign protein in a heterologous host. The ultimate challenge here is to design or manipulate polypeptide sequences (e.g., toward such desirable characteristics as enhanced nutritive value or more productive metabolic characteristics), but maintain a functional and stable three-dimensional conformation; this is impeded by our limited knowledge of the rules that govern protein folding and oligomer assembly and how these processes relate to a protein's ultimate stability in the cell. Thus, in addition to a characterization of protein targeting signals, more information is required about the structural features of proteins that allow for their stable accumulation in a particular subcellular compartment.

ACKNOWLEDGMENTS

I am grateful to Gad Galili, David G. Robinson, Brian W. Tague, Kenzo Nakamura, Roger Beachy, Jean-Marc Neuhaus, Bud Ryan, Faith Belanger, Jon T. Lindstrom, Aldo Ceriotti, Gerhard Saalbach, John J. Harada, Laura J. Olsen, Leonard Beevers, Maarten J. Chrispeels, Robert P. Donaldson, Natasha Raikhel, and Alan B. Bennett for making available their most recent data. Many thanks are also offered to Diana Elm for her prompt and accurate typing of the manuscript.

This article is dedicated to the memory of Lyle and Helen Anderson, who lived to have fun and show kindness to others, and to their surviving sons Gary and Wayne Anderson.
